Diagnosis of Pompe disease can be made by enzyme assay in dried blood spots, leukocytes, blood mononuclear cells, muscle, or cultured skin fibroblasts demonstrating deficient acid α-glucosidase activity. Gene sequencing showing 2 pathogenic variants in the *GAA* gene is confirmatory. The enzyme assay should be done in a laboratory with experience using maltose, glycogen, or 4-methylumbelliferyl-α-ᴅ -glucopyranoside (4MUG) as a substrate. The infantile form has a more severe enzyme deficiency than the late-onset forms. Detection of percent residual enzyme activity is captured in skin fibroblasts and muscle. Blood-based assays, especially dried blood spots, have the advantage of a rapid turnaround time and are being increasingly used as the first-line tissue to make a diagnosis. A muscle biopsy is often done with suspected muscle disease and a broad differential; it yields faster results and provides additional information about glycogen content and site of glycogen storage within and outside the lysosomes of muscle cells. However, a normal muscle biopsy *does not* exclude a diagnosis of Pompe disease. Late-onset patients show variability in glycogen accumulation in different muscles and within muscle fibers; muscle histology and glycogen content can vary depending on the site of muscle biopsy. There is also a high risk from anesthesia in infantile patients. An electrocardiogram can be helpful in making the diagnosis in suspected cases of the infantile form and should be done for patients suspected of having Pompe disease before any procedure requiring anesthesia, including muscle biopsy, is performed. Urinary glucose tetrasaccharides can be elevated in the urine of affected patients, and levels are extremely high in infantile patients. Availability of next-generation sequencing panels and whole exome sequencing allows for identification of additional patients with Pompe disease, especially when the diagnosis is ambiguous. **Prenatal diagnosis** using amniocytes or chorionic villi is available.

Treatment

Enzyme replacement therapy with recombinant human acid α-glucosidase (alglucosidase alfa) is available for treatment of Pompe disease. Recombinant acid α-glucosidase is capable of preventing deterioration or reversing abnormal cardiac and skeletal muscle functions (Fig. 105.3). ERT should be initiated as soon as possible across the disease spectrum, especially for babies with the infantile form, because the disease is rapidly progressive. Infants who are negative for cross-reacting immunologic material (CRIM) develop a high-titer antibody against the infused enzyme and respond to the ERT less favorably. Treatment using immunomodulating agents such as methotrexate, rituximab, and intravenous immune globulin (IVIG) have demonstrated efficacy in preventing the development of an immune response to ERT and immune tolerance. Nocturnal ventilatory support, when indicated, should be used; it has been shown to improve the quality of life and is particularly beneficial during a period of respiratory decompensation.

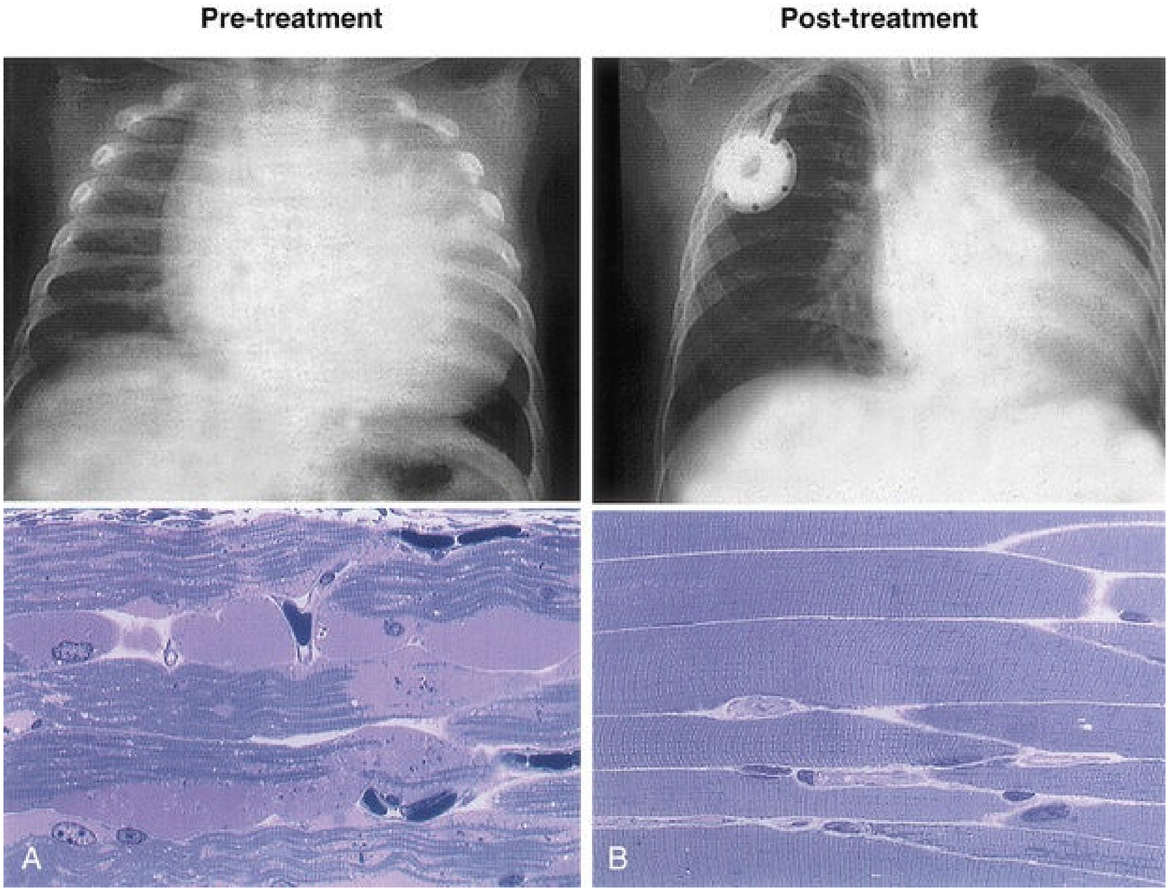

FIG. 105.3 Chest radiograph and muscle histology findings of an infantile-onset Pompe disease patient before (**A**) and after (**B**) enzyme replacement therapy. Note the decrease in heart size and muscle glycogen with the therapy. (Modified from Amalfitano A, Bengur AR, Morse RP, et al: Recombinant human acid alpha-glucosidase enzyme therapy for infantile glycogen storage disease type II: results of a phase I/II clinical trial, *Genet Med* 3:132–138, 2001.)

In addition to ERT, other adjunctive therapies have demonstrated benefit in Pompe patients. For patients with the late-onset disease, a high-protein diet may be beneficial. Respiratory muscle strength training has demonstrated improvements in respiratory parameters when combined with ERT. Submaximal exercise regimens are of assistance to improve muscle strength, pain, and fatigue. Other approaches are under clinical development to improve the safety and efficacy of enzyme delivery to affected tissues. These include use of chaperone molecules to enhance rhGAA delivery, and neoGAA, which is a second-generation ERT with a high number of mannose-6-phosphate (M6P) tags that enhances M6P receptor targeting and enzyme uptake. Gene therapy studies to correct the endogenous enzyme production pathways have shown promise.

Early diagnosis and treatment are necessary for optimal outcomes. Newborn screening using blood-based assays in Taiwan has resulted in early identification of Pompe cases and thus improved disease outcomes through the early initiation of ERT.

Glycogen Storage Diseases Mimicking Hypertrophic Cardiomyopathy (Danon Disease)

Danon disease is caused by pathogenic variants in the *LAMP2* gene, which leads to a deficiency of **lysosomal-associated membrane protein 2** (LAMP2). This leads to accumulation of glycogen in the heart and skeletal muscle, which presents primarily with hypertrophic cardiomyopathy and skeletal muscle weakness. Danon disease can be distinguished from the usual causes of hypertrophic cardiomyopathy (defects in sarcomere-protein genes) by their electrophysiologic abnormalities, particularly ventricular preexcitation and conduction defects. Patients present with cardiac symptoms, including chest pain, palpitations, syncope, and cardiac arrest, usually between ages 8 and 15 yr. Other clinical manifestations in Danon disease include peripheral pigmentary retinopathy, lens changes, and abnormal electroretinograms. This disorder is inherited in an X-linked dominant pattern. Diagnosis can be done by genetic testing for the *LAMP2* gene. The prognosis for LAMP2 deficiency is poor, with progressive end-stage heart failure early in adulthood. **Treatment** is directed toward management of symptoms in affected individuals, including management of cardiomyopathy, correction of arrhythmias, and physical therapy for muscle weakness. Cardiac transplantation has been tried successfully in some patients.

Adenosine Monophosphate–Activated Protein Kinase γ_2 Deficiency (PRKAG2 Deficiency)

AMP-activated protein kinase γ_2 (PRKAG2) deficiency is caused by pathogenic variants in the *PRKAG2* gene mapped to chromosome 7q36. *PRKAG2* is required for the synthesis of the enzyme AMP-activated protein kinase (AMPK), which regulates cellular pathways involved in ATP metabolism. Common presentations include hypertrophic cardiomyopathy and electrophysiologic abnormalities such as WPW syndrome, atrial fibrillation, and progressive atrioventricular block. Cardiac involvement is variable and includes supraventricular tachycardia, sinus bradycardia, left ventricular dysfunction, and even sudden cardiac death in some cases. In addition to cardiac involvement, there is a broad spectrum of phenotypic presentations including myalgia, myopathy, and seizures. Cardiomyopathy caused by *PRKAG2* variants usually allows for long-term survival, although a rare congenital form presenting in early infancy is associated with a rapidly fatal course. Cardiomyopathy in PRKAG2 syndrome often mimics that in other conditions, especially Pompe disease, and should be considered as a differential diagnosis in infants presenting with severe hypertrophic cardiomyopathy. **Treatment** is primarily symptomatic, including management of cardiac failure and correction of conduction defects.

Muscle Glycogen Synthase Deficiency

This GSD results from muscle glycogen synthase (**glycogen synthase I** , GYS1) deficiency. The gene GYS1 has been localized to chromosome 19q13.3. In the true sense, this is not a type of GSD because the deficiency of the enzyme leads to decreased glycogen stores. The disease is extremely rare and has been reported in 3 children of consanguineous parents of Syrian origin. Muscle biopsies showed lack of glycogen, predominantly oxidative fibers, and mitochondrial proliferation. Glucose tolerance was normal. Molecular study revealed a homozygous stop mutation (R462→ter) in the muscle glycogen synthase gene. The phenotype was variable in the 3 siblings and ranged from sudden cardiac arrest, muscle fatigability, hypertrophic cardiomyopathy, an abnormal heart rate, and hypotension while exercising, to mildly impaired cardiac function at rest.

Late-Onset Polyglucosan Body Myopathy (From *GYG1* Variants)

Late-onset polyglucosan body myopathy is an autosomal recessive, slowly progressive skeletal myopathy caused by pathogenic variants in the *GYG1* gene blocking **glycogenin-1** biosynthesis. There is a reduced or complete absence of glyogenin-1, which is a precursor necessary for glycogen formation. Polyglucosan accumulation in skeletal muscles causes adult-onset proximal muscle weakness, prominently affecting hip and shoulder girdles. Cardiac involvement is not seen. Compared with GSD IV–APBD, nervous system involvement is uncommon, although polyglucosan deposition is seen in both disorders. *GYG1* is mapped to chromosome 3q24. Muscle biopsies show PAS-positive storage material in 30–40% of muscle fibers. EM reveals the typical polyglucosan structure, consisting of ovoid form composed of partly filamentous material.

Type V Glycogen Storage Disease (Muscle Phosphorylase Deficiency, McArdle Disease)

GSD type V is caused by deficiency of **myophosphorylase** activity. Lack of this enzyme limits muscle ATP generation by glycogenolysis, resulting in muscle glycogen accumulation, and is the prototype of muscle energy disorders. A deficiency of myophosphorylase impairs the cleavage of glucosyl molecules from the straight chain of glycogen.

Clinical Manifestations

Symptoms usually first develop in late childhood or in the 2nd decade of life. Clinical heterogeneity is uncommon, but cases suggesting otherwise have been documented. Studies have shown that McArdle disease can manifest in individuals as old as 74, as well as in infancy in a fatal, early-onset form characterized by hypotonia, generalized muscle weakness, and respiratory complication. Symptoms are generally characterized by exercise intolerance with muscle cramps and pain. Symptoms are precipitated by 2 types of activity: brief, high-intensity exercise, such as sprinting or carrying heavy loads, and less intense but sustained activity, such as climbing stairs or walking uphill. Most patients can perform moderate exercise, such as walking on level ground, for long periods. Many patients experience a characteristic “second wind” phenomenon, with relief of muscle pain and fatigue after a brief period of rest. As a result of the underlying myopathy, these patients may be at risk for statin-induced myopathy and rhabdomyolysis. While patients typically experience episodic muscle pain and cramping from exercise, 35% of patients with McArdle disease report permanent pain that has a serious impact on sleep and other activities. Studies also suggest that there may also be a link between GSD V and variable cognitive impairment.

Approximately 50% of patients report burgundy-colored urine after exercise as a result of exercise-induced **myoglobinuria** secondary to **rhabdomyolysis** . Excessive myoglobinuria after intense exercise may precipitate acute renal failure.

Lab findings show elevated levels of serum CK at rest, which further increases after exercise. Exercise also elevates the levels of blood ammonia, inosine, hypoxanthine, and uric acid, which may be attributed to accelerated recycling of muscle purine nucleotides caused by insufficient ATP production. Type V GSD is an autosomal recessive disorder. The gene for muscle phosphorylase *(PYGM)* has been mapped to chromosome 11q13.

Diagnosis

The standard diagnosis for GSD V includes a muscle biopsy to measure glycogen content as well as enzyme and sequencing of *PYGM* . An ischemic exercise test offers a rapid diagnostic screening for patients with a metabolic myopathy. Lack of an increase in blood lactate levels and exaggerated blood ammonia elevations indicate muscle glycogenosis and suggest a defect in the conversion of muscle glycogen or glucose to lactate. The abnormal ischemic exercise response is *not limited* to type V GSD. Other muscle defects in glycogenolysis or glycolysis produce similar results (deficiencies of muscle phosphofructokinase, phosphoglycerate kinase, phosphoglycerate mutase, or LDH). An ischemic exercise test was once used to be a rapid diagnostic screening for suspected patients but was associated with severe complications and false-positive results. A nonischemic forearm exercise test with high sensitivity that is easy to perform and cost-effective has been determined to be indicative of muscle glycogenosis. However, as with the ischemic test, it cannot differentiate between abnormal exercise responses due to type V disease versus other defects in glycogenolysis or glycolysis or debranching enzyme (noted when the test is done after fasting).

The diagnosis is confirmed by molecular genetic testing of PYGM. A common nonsense variant, p.R49X in exon 1, is found in 90% of Caucasian patients, and a deletion of a single codon in exon 17 is found in 61% of Japanese patients. The p.R49X variant represents 55% of alleles in Spanish patients, whereas the p.W797R variant represents 14% and the p.G204S 9% of pathogenic alleles in the Spanish population. There seems to be an association between clinical severity of GSD V and presence of the D allele of the ACE insertion/deletion polymorphism. This may help explain the spectrum of phenotypic variability manifested in this disorder.

Treatment

Avoidance of strenuous exercise prevents the symptoms; regular and moderate exercise is recommended to improve exercise capacity. Glucose or sucrose given before exercise or injection of glucagon can greatly improve tolerance in these patients. A high-protein diet may increase muscle endurance, and low-dose creatine supplement has been shown to improve muscle function in some patients. The clinical response to creatine is dose dependent; muscle pain may increase on high doses of creatine supplementation. Vitamin B_6 supplementation reduces exercise intolerance and muscle cramps. Longevity is not generally affected.

Type VII Glycogen Storage Disease (Muscle Phosphofructokinase Deficiency, Tarui Disease)

Type VII GSD is caused by pathogenic variants in the *PFKM* gene, located on chromosome 12q13.1, which results in a deficiency of **muscle phosphofructokinase** enzyme. This enzyme is a key regulatory enzyme of glycolysis and is necessary for the ATP-dependent conversion of fructose-6-phosphate to fructose-1,6-diphosphate. Phosphofructokinase is composed of 3 isoenzyme subunits according to the tissue type and are encoded by different genes: (*PFKM* [M: muscle], *PFKL* [L: liver], and *PFKP* [P: platelet]). Skeletal muscle has only the M subunit, whereas red blood cells (RBCs) express a hybrid of L and M forms. In type VII GSD the M isoenzyme is defective, resulting in complete deficiency of enzyme activity in muscle and a partial deficiency in RBCs.

Type VII GSD is an autosomal recessive disorder with increased prevalence in individuals of Japanese ancestry and Ashkenazi Jews. A splicing defect and a nucleotide deletion in *PFKM* account for 95% of pathogenic variants in Ashkenazi Jews. Diagnosis based on molecular testing for the common variants is thus possible in this population.

Clinical Manifestations

Although the clinical picture is similar to that of type V GSD, the following features of type VII GSD are distinctive:

1. Exercise intolerance, which usually commences in childhood, is more severe than in type V disease and may be associated with nausea,

vomiting, and severe muscle pain; vigorous exercise causes severe muscle cramps and myoglobinuria.

2. Compensatory hemolysis occurs, as indicated by an increased level of serum bilirubin and an elevated reticulocyte count.
3. Hyperuricemia is common and exaggerated by muscle exercise to a greater degree than that observed in type V or III GSD.
4. An abnormal polysaccharide is present in muscle fibers; it is PAS positive but resistant to diastase digestion.
5. Exercise intolerance is especially worse after carbohydrate-rich meals because the ingested glucose prevents lipolysis, thereby depriving muscle of fatty acid and ketone substrates. This is in contrast to patients with type V disease, who can metabolize blood borne glucose derived from either endogenous liver glycogenolysis or exogenous glucose; indeed, glucose infusion improves exercise tolerance in type V patients.
6. The “second wind” phenomenon is absent because of the inability to break down blood glucose.

Several rare type VII variants occur. One variant presents in infancy with hypotonia and limb weakness and proceeds to a rapidly progressive myopathy that leads to death by 4 yr of age. A 2nd variant occurs in infancy and results in congenital myopathy and arthrogryposis with a fatal outcome. A 3rd variant presents in infancy with hypotonia, mild developmental delay, and seizures. An additional presentation is *hereditary nonspherocytic hemolytic anemia* . Although these patients do not experience muscle symptoms, it remains unclear whether these symptoms will develop later in life. One variant presents in adults and is characterized by a slowly progressive, fixed muscle weakness rather than cramps and myoglobinuria. It may also cause mitral valve thickening from glycogen buildup.

Diagnosis

To establish a diagnosis, a biochemical or histochemical demonstration of the enzymatic defect in the muscle is required. The absence of the M isoenzyme of phosphofructokinase can also be demonstrated in muscle, blood cells, and fibroblasts. Gene sequencing can identify pathogenic variants for the phosphofructokinase gene.

Treatment

There is no specific treatment. Strenuous exercise should be avoided to prevent acute episodes of muscle cramps and myoglobinuria. Consuming simple carbohydrates before strenuous exercise may benefit by improving exercise tolerance. A ketogenic diet has been reported to show clinical improvement in a patient with infantile GSD VII. Drugs such as statins should be avoided. Precautionary measures should be taken to avoid hyperthermia while undergoing anesthesia. Carbohydrate meals and glucose infusions have demonstrated worsening symptoms because of the body's inability to utilize glucose. The administered glucose tends to lower the levels of fatty acids in the blood, a primary source of muscle fuel.

Muscle-Specific Phosphorylase Kinase Deficiency (From *PHKA1* Variants)

A few cases of PhK deficiency restricted to muscle are known. Patients, both male and female, present either with muscle cramps and myoglobinuria with exercise or with progressive muscle weakness and atrophy. PhK activity is decreased in muscle but normal in liver and blood cells. There is no hepatomegaly or cardiomegaly. This is inherited in an X-linked or autosomal recessive manner. The gene for the muscle-specific form α subunit (αM) is located at Xq12. Pathogenic variants of the gene have been found in some male patients with this disorder. The gene for muscle γ subunit (γM, *PHKG1*) is on chromosome 7p12. No pathogenic variants in this gene have been reported so far.

Other Muscle Glycogenoses With Muscle Energy Impairment

Six additional defects in enzymes—phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase, fructose-1,6-bisphosphate aldolase A, muscle pyruvate kinase, and β-enolase in the pathway of the terminal glycolysis—cause symptoms and signs of muscle energy impairment similar to those of types V and VII GSD. The failure of blood lactate to increase in response to exercise is a useful diagnostic test and can be used to differentiate muscle glycogenoses from disorders of lipid metabolism, such as carnitine palmitoyltransferase II deficiency and very-long-chain acyl-CoA dehydrogenase deficiency, which also cause muscle cramps and myoglobinuria. Muscle glycogen levels can be normal in the disorders affecting terminal glycolysis, and assaying the muscle enzyme activity is needed to make a definitive diagnosis. There is no specific treatment (see preceding Treatment section).

Defects in Galactose Metabolism

Priya S. Kishnani, Yuan-Tsong Chen

Keywords

galactose
lactose
galactosemia
transferase

galactokinase
epimerase
reducing substance

Milk and dairy products contain **lactose** , the major dietary source of galactose. The metabolism of galactose produces fuel for cellular metabolism through its conversion to glucose-1-phosphate (see Table 105.1). Galactose also plays an important role in the formation of galactosides, which include glycoproteins, glycolipids, and glycosaminoglycans. **Galactosemia** denotes the elevated level of galactose in the blood and is found in 3 distinct inborn errors of galactose metabolism in 1 of the following enzymes: galactose-1-phosphate uridyl transferase, galactokinase, and uridine diphosphate galactose-4-epimerase. The term galactosemia, although adequate for the deficiencies in any of these disorders, generally designates the *transferase* deficiency.

Galactose-1-Phosphate Uridyl Transferase Deficiency Galactosemia

Two forms of the deficiency exist: infants with complete or near-complete deficiency of the enzyme (classic galactosemia) and those with partial transferase deficiency. **Classic galactosemia** is a serious disease with onset of symptoms typically by the 2nd half of the 1st wk of life. The incidence is predicted to be 1 in 60,000 live births. The newborn infant receives high amounts of lactose (up to 40% in breast milk and certain formulas), which consists of equal parts of glucose and galactose. Without the transferase enzyme, the infant is unable to metabolize galactose-1-phosphate, the accumulation of which results in injury to kidney, liver, and brain. This injury may begin prenatally in the affected fetus by transplacental galactose derived from the diet of the heterozygous mother or by endogenous production of galactose in the fetus.

Clinical Manifestations

The diagnosis of uridyl transferase deficiency should be considered in newborn or young infants with any of the following features within a few days or weeks after birth: jaundice, hepatomegaly, vomiting, hypoglycemia, seizures, lethargy, irritability, feeding difficulties, poor weight gain or failure to regain birthweight, and aminoaciduria. Untreated children may show nuclear cataracts, vitreous hemorrhage, hepatic failure, cirrhosis, ascites, splenomegaly, or intellectual disability. Patients with galactosemia are at increased risk for *Escherichia coli* neonatal sepsis; the onset of sepsis often precedes the diagnosis of galactosemia. Pseudotumor cerebri can occur and cause a bulging fontanel. Complete withdrawal of lactose from the diet results in improvement of the acute symptoms. If untreated, death from liver and kidney failure and sepsis may follow within days. When the diagnosis is not made at birth, damage to the liver (cirrhosis) and brain (intellectual disability) becomes increasingly severe and irreversible.

Partial transferase deficiency is generally asymptomatic. It is more common than classic galactosemia and is diagnosed in newborn screening because of moderately elevated blood galactose and/or low transferase activity. Galactosemia should be considered for the newborn or young infant who is not thriving or who has any of the preceding findings. Light and electron microscopy of hepatic tissue reveals fatty infiltration, the formation of pseudoacini, and eventual macronodular cirrhosis. These changes are consistent with a metabolic disease but do not indicate the precise enzymatic defect.

Diagnosis

The *initial* diagnosis of galactosemia is done by demonstration of a **reducing substance** in several urine specimens collected while the patient is on a diet containing human milk, cow's milk, or any other formula containing lactose. The reducing substance detected in urine by Clinitest (e.g., glucose, galactose) can be identified by chromatography or an enzymatic test specific for galactose. Galactose can be detected in urine, provided the milk feeding was within the last few hours and the child is not vomiting excessively. Clinistix urine test results are usually negative because the test relies on the action of glucose oxidase, which is specific for glucose but is nonreactive with galactose. Amino acids may be detected in urine since they are excreted together with glucose because of a proximal renal tubular syndrome. Since galactose is injurious to persons with galactosemia, diagnostic challenge tests dependent on administering galactose orally or intravenously should not be used. *Direct enzyme assay using erythrocytes establishes the diagnosis.* The clinician needs to confirm that the patient did not receive a blood transfusion before the collection of the blood sample, because a diagnosis could be missed. A novel method utilizes nonradioactive ultraviolet (UV) light and high-performance liquid chromatography (HPLC) to accurately detect levels of galactose-1-phosphate uridyl transferase in erythrocytes.

Genetics

Transferase deficiency is an autosomal recessive disorder. Based on newborn screening in the United States, the frequency of the disease is approximately 1 in 47,000 live births. There are several enzymatic variants of galactosemia. The *Duarte variant,* a single– amino acid substitution (p.N314D), has diminished RBC enzyme activity (50% of normal), but usually is of no clinical significance. This variant is the most common, with a carrier frequency of 12% in the general population. Those who are heterozygous for the Duarte variant of galactosemia typically have 25% of normal galactose activity, few symptoms, elevated metabolites, and no need for intervention. Other similar variants expressing little enzyme activity typically require no intervention. Some black patients have milder symptoms despite the absence of measurable transferase activity in erythrocytes; these patients retain 10% enzyme activity in liver and intestinal mucosa, whereas most white patients have no detectable activity in any of these tissues. More than 230 identifiable pathogenic variants have been associated with transferase deficiency. In blacks, 62% of alleles are represented by the p.S135L variant, a variant that is responsible for a milder disease course. In the white population, 70% of alleles are represented by the p.Q188R and p.K285N missense variants and are associated with severe disease. Carrier testing and prenatal diagnosis can be performed by direct enzyme analysis of amniocytes or chorionic villi; testing can also be DNA based.

Treatment and Prognosis

With the availability of newborn screening for galactosemia, it is possible to identify and treat patients earlier than before. All galactose-containing foods should be removed from the diet on initial suspicion of galactosemia. Various non–lactose-containing milk substitutes are available (casein hydrolysates, soybean-based formula). Elimination of galactose from the diet along with adequate calcium supplementation reverses growth failure and renal and hepatic dysfunction. Cataracts regress, and most patients have no impairment of vision.

Early diagnosis and treatment have improved the prognosis of galactosemia. On long-term follow-up, however, patients still manifest ovarian failure with primary or secondary amenorrhea, decreased bone mineral density, developmental delay, and learning disabilities that increase in severity with age. *Hypergonadotropic hypogonadism* is reported in 80% to >90% of female patients with classic galactosemia. Although most women with classic galactosemia are infertile when they reach childbearing age, a small number have given birth. Most patients manifest speech disorders, whereas a smaller number demonstrate poor growth and impaired motor function and balance (with or without overt ataxia). The relative control of galactose-1-phosphate levels does not always correlate with long-term outcome, leading to the belief that other factors, such as elevated galactitol, decreased uridine diphosphate galactose (a donor for galactolipids and proteins), and endogenous galactose production may be responsible.

Galactokinase Deficiency

The deficient enzyme is **galactokinase** , which normally catalyzes the phosphorylation of galactose. The principal metabolites accumulated are galactose and galactitol. Two genes are reported to encode galactokinase: *GK1* on chromosome 17q24 and *GK2* on chromosome 15. **Cataracts** are usually the sole manifestation of galactokinase deficiency; pseudotumor cerebri is a rare complication. The affected infant is otherwise asymptomatic. Heterozygous carriers may be at risk for presenile cataracts. Lab findings show an increased concentration of blood galactose levels, provided the infant has been fed a lactose-containing formula. The diagnosis is made by demonstrating an absence of galactokinase activity in erythrocytes or fibroblasts. Transferase activity is normal. Treatment is dietary restriction of galactose.

Uridine Diphosphate Galactose-4-Epimerase Deficiency

There are 2 distinct forms of **epimerase** deficiency. The first is a **benign** form that is diagnosed incidentally through newborn screening programs. Affected individuals are asymptomatic because the enzyme deficiency is limited to leukocytes and erythrocytes. This form does not require treatment. The second variety is **severe** because the epimerase deficiency is more generalized. Clinical manifestations resemble transferase deficiency, with the additional symptoms of hypotonia and nerve deafness. Clinical symptoms improve with restriction of galactose in diet. Although the severe form of galactosemia is rare, it must be considered in a symptomatic patient with measurable galactose-1-phosphate who has normal transferase activity. The abnormally accumulated metabolites are similar to those in transferase deficiency; however, there is also an increase in cellular uridine diphosphate (UDP) galactose. Diagnosis is confirmed by the assay of epimerase in erythrocytes.

Patients with the severe form of epimerase deficiency cannot synthesize UDP galactose from UDP glucose and are galactose dependent. Because galactose is an essential component of many nervous system structural proteins, patients are placed on a galactose-restricted diet rather than a galactose-free diet.

Infants with the mild form of epimerase deficiency have not required treatment. It is advisable to follow urine specimens for reducing substances and exclude aminoaciduria within a few weeks of diagnosis while the infant is still on lactose-containing formula.

The gene for UDP galactose-4-epimerase *(GALE)* is located on chromosome 1 at 1p36. Carrier detection is possible by measurement of epimerase activity in the erythrocytes. **Prenatal diagnosis** for the severe form of epimerase deficiency can be done using an enzyme assay of cultured amniotic fluid cells.

aldolase
hypoglycemia

Two inborn errors are known in the specialized pathway of fructose metabolism: benign or essential fructosuria and hereditary fructose intolerance. Fructose-1,6-bisphosphatase deficiency, although strictly speaking not a defect of the specialized fructose pathway, is discussed in Chapter 105.4 .

Deficiency of Fructokinase (Essential or Benign Fructosuria)

Deficiency of fructokinase is not associated with any clinical manifestations. **Fructosuria** is an accidental finding usually made because the asymptomatic patient's urine contains a reducing substance. No treatment is necessary, and the prognosis is excellent. Inheritance is autosomal recessive with an incidence of 1 in 120,000 live births. The gene encoding fructokinase (*KHK)* is located on chromosome 2p23.3.

Fructokinase catalyzes the first step of metabolism of dietary fructose: conversion of fructose to fructose-1-phosphate (see Fig. 105.1). Without this enzyme, ingested fructose is not metabolized; its level is increased in the blood, and it is excreted in urine because practically no renal threshold exists for fructose. Clinitest results reveal the urinary reducing substance, which can be identified as fructose by chromatography.

Deficiency of Fructose-1,6-Bisphosphate Aldolase (Aldolase B, Hereditary Fructose Intolerance)

Deficiency of fructose-1,6-bisphosphate aldolase (**aldolase-B**) is a severe condition of infants caused by a deficiency of aldolase B activity in the liver, kidney, and intestine. This enzyme catalyzes the hydrolysis of fructose-1,6-bisphosphate into triose phosphate and glyceraldehyde phosphate. The same enzyme also hydrolyzes fructose-1-phosphate. In the absence of enzyme activity, there is a rapid accumulation of fructose-1-phosphate, which presents with severe symptoms when fructose-containing food is ingested.

Epidemiology and Genetics

The exact incidence of **hereditary fructose intolerance (HFI)** is unknown but is estimated to be as high as 1 in every 26,000 live births. HFI is inherited in an autosomal recessive manner. The *ALDOB* gene is mapped to chromosome 9q22.3. At least 40 pathogenic variants causing HFI are known. The most common pathogenic variant identified in northern Europeans is a single missense variant, a G→C transversion in exon 5 resulting in the normal alanine at position 149 being replaced by proline. This variant, along with 2 other missense variants (p.A174D and p.N334K), account for 80–85% of HFI in Europe and the United States. Diagnosis of HFI can be made by direct DNA analysis for the common variants and phosphorus magnetic resonance spectroscopy.

Clinical Manifestations

Affected individuals remain asymptomatic until fructose or sucrose (table sugar) is introduced in diet (usually from fruit, fruit juice, or sweetened cereal). Signs and symptoms typically manifest in infancy when foods or formulas containing these sugars are introduced. Certain patients are very sensitive to fructose, whereas others can tolerate moderate intakes (up to 250 mg/kg/day). The average intake of fructose in Western societies is 1-2 g/kg/day. Early clinical manifestations resemble galactosemia and include jaundice, hepatomegaly, vomiting, lethargy, irritability, and convulsions. There may also be a higher incidence of *celiac disease* in HFI patients (>10%) than in the general population (1–3%). As they grow older, patients usually develop an aversion to fructose-containing foods due to associated symptoms of nausea, vomiting, and abdominal pain.

Characteristic lab findings include lactic acidosis, hypophosphatemia, hyperuricemia, and hypermagnesemia. A prolonged clotting time, hypoalbuminemia, elevation of bilirubin and transaminase levels, and proximal tubular dysfunction are also seen. Acute fructose ingestion produces symptomatic hypoglycemia; the higher the intake, the more severe the clinical picture. Chronic ingestion results in failure to thrive and hepatic disease. If the intake of fructose persists, hypoglycemic episodes recur, leading to progressive renal and hepatic failure and eventually death.

Diagnosis

The presence of a reducing substance in urine during an acute episode raises the possibility of HFI. Oral fructose challenge is *no longer* considered a diagnostic approach because of high risk to the patient, who can become acutely ill after the test. Definitive diagnosis is made by demonstration of 2 pathogenic variants in *ALDOB* on molecular genetic testing. A common pathogenic variant (substitution of *Pro* for *Ala* at position 149) accounts for 53% of HFI alleles worldwide. An alternative is to show deficient hepatic fructose 1-phosphate aldolase (aldolase B) activity on liver biopsy.

Treatment

Acute episodes are managed symptomatically by correcting hypoglycemia with IV glucose (dextrose) administration, providing supportive treatment of hepatic insufficiency, and correcting metabolic acidosis. Complete elimination of fructose usually rapidly reverses symptoms and results in normalization of related metabolic disturbances. The cornerstone of long-term treatment is the complete restriction of all sources of sucrose, fructose, and sorbitol from the diet. It may be difficult because these sugars are widely used additives, found even in most medicinal preparations. With treatment, liver and kidney dysfunction improves, and catch-up in growth is common. Intellectual development is usually unimpaired. As the patient matures, symptoms become milder even after fructose ingestion; the long-term prognosis is good. Because of voluntary dietary avoidance of sucrose, affected patients have few dental caries. Care should be taken to avoid fructose-containing IV fluids during hospitalizations.

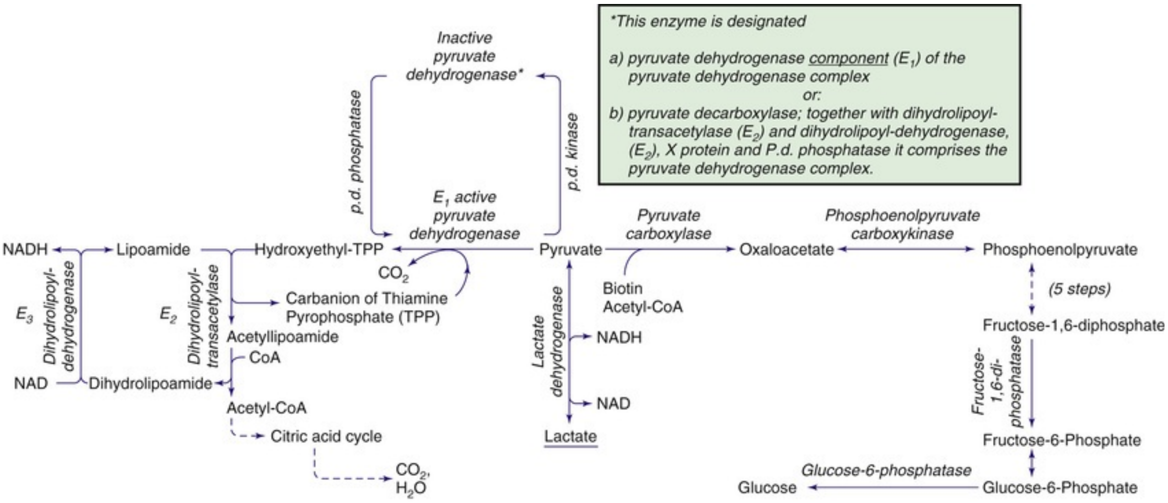
Defects in Intermediary Carbohydrate Metabolism Associated With Lactic Acidosis

Priya S. Kishnani, Yuan-Tsong Chen

Keywords

pyruvate
lactic acidosis
lactate
biotin
mitochondria
respiratory chain
Leigh disease
oxidation, retinopathy

Lactic acidosis (**type B3**) occurs with defects of carbohydrate metabolism that interfere with the conversion of pyruvate to glucose via the pathway of gluconeogenesis or to carbon dioxide and water via the mitochondrial enzymes of the Krebs cycle. Fig. 105.4 depicts the relevant metabolic pathways. Type I GSD, fructose-1,6-diphosphatase deficiency, and phosphoenolpyruvate carboxylase deficiency are disorders of gluconeogenesis associated with lactic acidosis. Pyruvate dehydrogenase complex deficiency, respiratory chain defects, and pyruvate carboxylase deficiency are disorders in the pathway of pyruvate metabolism causing lactic acidosis. Lactic acidosis (type B3) can also occur in defects of fatty acid oxidation, organic acidurias (see Chapters 103.6 , 103.10 , and 104.1), or biotin utilization diseases (type B3) (Table 105.2). These disorders are easily distinguishable by the presence of abnormal acyl carnitine profiles, amino acids in the blood, and unusual organic acids in the urine. Blood lactate, pyruvate, and acyl carnitine profiles, and the presence of these unusual urine organic acids should be determined in infants and children with unexplained acidosis, especially if there is an increase of anion gap.



*This enzyme is designated

The pyruvate dehydrogenase complex comprises, in addition to E_1, E_2, and E_3, an extra lipoate-containing protein (not shown), called protein X, and pyruvate dehydrogenase phosphatase.

Table 105.2

Causes of Type B Lactic Acidosis

Type B1—Underlying Diseases

Renal failure
Hepatic failure
Diabetes mellitus
Malignancy
Systemic inflammatory response syndrome
Human immunodeficiency virus

Type B2—Drugs and Toxins

Acetaminophen
Alcohols—ethanol, methanol, diethylene glycol, isopropanol, and propylene glycol
Antiretroviral nucleoside analogs—zidovudine, didanosine, and lamivudine
β-Adrenergic agonists—epinephrine, ritodrine, and terbutaline
Biguanides—phenformin and metformin

Cocaine, methamphetamine
Cyanogenic compounds—cyanide, aliphatic nitriles, and nitroprusside
Diethyl ether
Fluorouracil
Halothane
Iron
Isoniazid
Linezolid
Nalidixic acid
Niacin
Propopol
Salicylates
Strychnine
Sugars and sugar alcohols—fructose, sorbitol, and xylitol
Sulfasalazine
Total parenteral nutrition
Valproic acid
Vitamin deficiencies—thiamine and biotin

Type B3—Inborn Errors of Metabolism

Glucose-6-phosphatase deficiency (von Gierke disease)
Fructose-1,6-diphosphatase deficiency
Phosphoenolpyruvate carboxykinase deficiency
Pyruvate carboxylase deficiency
Pyruvate dehydrogenase complex (PDHC) deficiency
Krebs cycle defects
Methylmalonic aciduria and other organic acidemias
Kearns-Sayre syndrome
Pearson syndrome
Barth syndrome
Mitochondrial DNA depletion syndromes
Nuclear DNA respiratory chain defects
Mitochondrial DNA respiratory defects
Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)
Myoclonic epilepsy with ragged red fibers (MERRF)

Adapted from Vernon C, LeTourneau JL: Lactic acidosis: recognition, kinetics, and associated prognosis, Crit Care Clin 26:255–283, 2010 (Box 1, p 264).

Lactic acidosis unrelated to an enzymatic defect occurs in hypoxemia (**type A** lactic acidosis). In this case, as well as in defects in the respiratory chain, the serum pyruvate concentration may remain normal (<1.0 mg/dL, with increased lactate:pyruvate ratio), whereas pyruvate is usually increased when lactic acidosis results from an enzymatic defect in gluconeogenesis or pyruvate dehydrogenase complex (both lactate and pyruvate are increased, and the ratio is normal). Lactate and pyruvate should be measured in the same blood specimen and on multiple blood specimens obtained when the patient is symptomatic because lactic acidosis can be intermittent. Fig. 105.5 is an algorithm for the differential diagnosis of lactic acidosis. Lactic acidosis is also noted with various underlying diseases (**type B1**) and drugs or toxins (**type B2**) (Table 105.2).

FIG. 105.5 Algorithm of the differential diagnosis of lactic acidosis.

Disorders of Gluconeogenesis

Deficiency of Glucose-6-Phosphatase (Type I Glycogen Storage Disease)

Type I GSD is the only glycogenosis associated with significant **lactic acidosis** . The chronic metabolic acidosis predisposes these patients to osteopenia; after prolonged fasting, the acidosis associated with hypoglycemia is a life-threatening condition (see Chapter 105.1).

Fructose-1,6-Diphosphatase Deficiency

Fructose-1,6-diphosphatase deficiency impairs the formation of glucose from all gluconeogenic precursors, including dietary fructose. Hypoglycemia occurs when glycogen reserves are limited or exhausted. The **clinical manifestations** are characterized by life-threatening episodes of acidosis, hypoglycemia, hyperventilation, convulsions, and coma. In about half the cases, the deficiency presents in the 1st wk of life. In infants and small children, episodes are triggered by febrile infections and gastroenteritis if oral food intake decreases. The frequency of the attacks decreases with age. Laboratory findings include low blood glucose, high lactate and uric acid levels, and metabolic acidosis. In contrast to HFI, there is usually no aversion to sweets; renal tubular and liver function is normal.

The **diagnosis** is established by demonstrating an enzyme deficiency in either liver or intestinal biopsy. The enzyme defect can also be demonstrated in leukocytes in some cases. The gene coding for fructose-1,6-diphosphatase *(FBP1)* is located on chromosome 9q22; pathogenic variants are characterized, making carrier detection and prenatal diagnosis possible. **Treatment** of acute attacks consists of correction of hypoglycemia and acidosis by IV glucose infusion; the response is usually rapid. Avoidance of fasting, aggressive management of infections, and restriction of fructose and sucrose from the diet can prevent further episodes. For long-term prevention of hypoglycemia, a slowly released carbohydrate such as cornstarch is useful. Patients who survive childhood develop normally.

Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase (**PEPCK**) is a key enzyme in gluconeogenesis. It catalyzes the conversion of oxaloacetate to phosphoenolpyruvate (see Fig. 105.4). PEPCK deficiency is both a mitochondrial enzyme deficiency and a cytosolic enzyme deficiency, encoded by 2 distinct genes.

PEPCK deficiency has been reported in only a few cases. The clinical features are heterogeneous, with hypoglycemia, lactic acidemia, hepatomegaly, hypotonia, developmental delay, and failure to thrive as the major manifestations. There may be multisystem involvement, with neuromuscular deficits, hepatocellular damage, renal dysfunction, and cardiomyopathy. The **diagnosis** is based on the reduced activity of PEPCK in liver, fibroblasts, or lymphocytes. Fibroblasts and lymphocytes are not suitable for diagnosing the cytosolic form of PEPCK deficiency because these tissues possess only mitochondrial PEPCK. To avoid hypoglycemia, patients should receive **treatment** with slow-release carbohydrates such as cornstarch, and fasting should be avoided.

Disorders of Pyruvate Metabolism

Pyruvate is formed from glucose and other monosaccharides, from lactate, and from alanine. It is metabolized through 4 main enzyme systems: lactate dehydrogenase, alanine transaminase, pyruvate carboxylase, and pyruvate dehydrogenase complex. Deficiency of the M subunit of LDH causes exercise intolerance and myoglobinuria (see Chapter 105.1).

Pyruvate Dehydrogenase Complex Deficiency

After entering the mitochondria, pyruvate is converted into acetyl-CoA by the pyruvate dehydrogenase complex (**PDHC**), which catalyzes the oxidation of pyruvate to acetyl-CoA, which then enters the tricarboxylic acid cycle for ATP production. The complex comprises 5 components: **E_1** , an α-ketoacid decarboxylase; **E_2** , a dihydrolipoyl transacylase; **E_3** , a dihydrolipoyl dehydrogenase; **protein X** , an extra lipoate-containing protein; and pyruvate dehydrogenase phosphatase. The most common is a defect in the E_1 (see Fig. 105.4).

Deficiency of the PDHC is the most common of the disorders leading to lactic acidemia and CNS dysfunction. The CNS dysfunction occurs because the brain obtains its energy primarily from oxidation of glucose. Brain acetyl-CoA is synthesized almost exclusively from pyruvate.

The E_1 defects are caused by pathogenic variants in the gene coding for E_1 α subunit, which is X-linked dominant. Although X-linked, its deficiency is a problem in both male and female patients, despite only one E_1 α allele in females carrying a variant.

Clinical Manifestations

PDHC deficiency has a wide spectrum of presentations, from the most severe neonatal presentation to a mild late-onset form. The **neonatal onset** is associated with lethal lactic acidosis, white matter cystic lesions, agenesis of the corpus callosum, and the most severe enzyme deficiency. **Infantile onset** can be lethal or associated with psychomotor delay and chronic lactic acidosis, cystic lesions in the brainstem and basal ganglia, and pathologic features resembling **Leigh disease** (see later and Chapter 616.2). Neurologic symptoms in PDHC can be categorized into 2 groups: abnormal brain development, seen in both males and females, and brain lesions and epilepsy, seen in male patients only. Older children, usually boys, may have less acidosis, have greater enzyme activity, and manifest ataxia with high-carbohydrate diets. Intelligence may be normal. Patients of all ages may have facial dysmorphology, features similar to those of fetal alcohol syndrome.

The **E_2** and **protein X–lipoate** defects are rare and result in severe psychomotor retardation. The **E_3 lipoamide dehydrogenase** defect leads to deficient activity not only in the PDHC, but also in the α-ketoglutarate and branched-chain ketoacid dehydrogenase complexes. This deficiency is more common in the Ashkenazi Jewish population. The reactive oxygen species generated by the pathogenic variants responsible for lipoamide dehydrogenase deficiency may in fact explain certain disease characteristics and suggest the utility of antioxidant therapy. **Pyruvate dehydrogenase phosphatase** deficiency has also been reported. These other PDHC defects have clinical manifestations within the variable spectrum associated with PDHC deficiency caused by E_1 deficiency.

Treatment

The general prognosis is poor, except in rare patients in whom variants are associated with altered affinity for thiamine pyrophosphate, who may respond to thiamine supplementation. Because carbohydrates can aggravate lactic acidosis, a ketogenic diet is recommended. The diet has been found to lower the blood lactate level; the long-term benefit to patient outcome is unclear. A potential treatment strategy is to maintain any residual PDHC in its active form by oral administration of **dichloroacetate** , an inhibitor of E_1 kinase. Beneficial effects of controlling postprandial lactic acidosis have been shown in some patients. Young children with congenital acidosis generally tolerate dichloroacetate well, but continued exposure is associated with peripheral neuropathy, a condition that could be attributable to the drug or the disease.

Deficiency of Pyruvate Carboxylase

Pyruvate carboxylase is a mitochondrial, biotin-containing enzyme essential in the process of gluconeogenesis; it catalyzes the conversion of pyruvate to oxaloacetate. The enzyme is also essential for Krebs cycle function as a provider of oxaloacetate and is involved in lipogenesis and formation of nonessential amino acids. **Clinical manifestations** of this deficiency have varied from neonatal severe lactic acidosis accompanied by hyperammonemia, citrullinemia, and hyperlysinemia (**type B**) to late-onset mild to moderate lactic acidosis and developmental delay (**type A**). In both types, patients who survived usually had severe psychomotor retardation with seizures, spasticity, and microcephaly. Some patients have pathologic changes in the brainstem and basal ganglia that resemble **Leigh disease** . The clinical severity appears to correlate with the level of the residual enzyme activity. A “benign” form of pyruvate carboxylase deficiency has also been described, characterized by recurrent attacks of lactic acidosis and mild neurologic deficits (**type C**). Laboratory findings are characterized by elevated levels of blood lactate, pyruvate, alanine, and ketonuria. In the case of type B, blood ammonia, citrulline, and lysine levels are also elevated, which might suggest a primary defect of the urea cycle. The mechanism is likely caused by depletion of oxaloacetate, which leads to reduced levels of aspartate, a substrate for argininosuccinate synthase in the urea cycle (see Chapter 103.12). The gene for pyruvate carboxylase (*PC)* is located on chromosome 11q13.4-q13.5, and about 15 pathogenic variants have been identified.

Treatment consists of avoidance of fasting and eating a carbohydrate meal before bedtime. During acute episodes of lactic acidosis, patients should receive continuous IV glucose. Aspartate and citrate supplements restore the metabolic abnormalities; whether this treatment can prevent the neurologic deficits is not known. Liver transplantation has been attempted; its benefit remains unknown. **Diagnosis** of pyruvate carboxylase deficiency is made by the measurement of enzyme activity in liver or cultured skin fibroblasts and must be differentiated from holocarboxylase synthase or biotinidase deficiency.

Deficiency of Pyruvate Carboxylase Secondary to Deficiency of Holocarboxylase Synthase or Biotinidase

Deficiency of either holocarboxylase synthase (**HCS**) or biotinidase, which are enzymes of biotin metabolism, result in multiple-carboxylase deficiency (pyruvate carboxylase and other biotin-requiring carboxylases and metabolic reactions) and in **clinical manifestations** associated with the respective deficiencies, as well as rash, lactic acidosis, and alopecia (see Chapter 103.6). The course of HCS or biotinidase deficiency can be protracted, with intermittent exacerbation of chronic lactic acidosis, failure to thrive, seizures, and hypotonia leading to spasticity, lethargy, coma, and death. Auditory and optic nerve dysfunction can lead to deafness and blindness, respectively. Late-onset milder forms have also been reported. Laboratory findings include metabolic acidosis and abnormal organic acids in the urine. In HCS deficiency, biotin concentrations in plasma and urine are normal. **Diagnosis** can be made in skin fibroblasts or lymphocytes by assay for HCS activity, and in the case of biotinidase, in the serum by a screening blood spot.

Treatment consists of biotin supplementation, 5-20 mg/day, and is generally effective if treatment is started before the development of brain damage. Patients identified through newborn screening and treated with biotin have remained asymptomatic.

Both enzyme deficiencies are autosomal recessive disorders. The incidence of HCS deficiency is approximately 1 in 87,000 live births. *HCS* and biotinidase *(BTD)* are located on chromosome 21q22 and 3p25, respectively. Ethnic-specific pathogenic variants in the *HCS* gene have been identified. Two common pathogenic variants (del7/ins3 and p.R538C) in the *BTD* account for 52% of all pathogenic alleles in symptomatic patients with biotinidase deficiency.

Mitochondrial Respiratory Chain Defects (Oxidative Phosphorylation Disease)

The mitochondrial respiratory chain catalyzes the oxidation of fuel molecules and transfers the electrons to molecular oxygen with concomitant energy transduction into adenosine triphosphate (**oxidative phosphorylation**) (see Chapter 106). The respiratory chain produces ATP from adenosine diphosphate and inorganic phosphate utilizing the energy from electrons transferred from nicotinamide adenine dinucleotide (NADH) or flavin adenine dinucleotide and includes 5 specific complexes (I: NADH–coenzyme Q reductase; II: succinate–coenzyme Q reductase; III: coenzyme QH_2 cytochrome-*c* reductase; IV: cytochrome-*c* oxidase; V: ATP synthase). Each complex is composed of 4-35 individual proteins and, with the exception of complex II (which is encoded solely by nuclear genes), is encoded by nuclear or mitochondrial DNA (inherited only from the mother by mitochondrial inheritance). Defects in any of these complexes or assembly systems produce chronic lactic acidosis, presumably because of a change of the reduction-oxidation state with increased concentrations of NADH (see Table 105.3).

In contrast to PDHC or pyruvate carboxylase deficiency, skeletal muscle and heart are usually involved in the respiratory chain disorders. On muscle biopsy, **ragged red fibers** indicating mitochondrial proliferation are very suggestive when present (see Fig. 105.5). Because of the ubiquitous nature of oxidative phosphorylation, a defect of the mitochondrial respiratory chain accounts for a vast array of clinical manifestations and should be considered in patients in all age-groups presenting with multisystem involvement. Some deficiencies resemble **Leigh disease** , whereas others cause infantile myopathies such as **MELAS** (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes), **MERRF** (myoclonic epilepsy and ragged red fibers), and **Kearns-Sayre syndrome** (external ophthalmoplegia, acidosis, retinal degeneration, heart block, myopathy, and high cerebrospinal fluid protein) (Table 105.3) (see Chapters 616.2 and 629.4). There is a higher incidence of psychiatric disorders in adults with a primary oxidative phosphorylation disease than in the general population. Elevated serum growth and differentiation factor (GDF)-15 levels help screen for mitochondrial disorders.

Diagnosis requires demonstration of abnormalities of oxidative phosphorylation enzyme complex activities in tissues or of mitochondrial DNA or a nuclear gene coding for mitochondrial functions, or both (Fig. 105.6). Muscle histology, including EM, can detect ragged red fibers and other abnormalities typical of mitochondrial myopathies. Analysis of oxidative phosphorylation complexes I-IV from intact mitochondria isolated from fresh skeletal muscle is the most sensitive assay for mitochondrial disorders; however, electron transport chain testing of flash-frozen muscle provides an alternative approach when fresh muscle testing is not available. Next-generation sequencing of mitochondrial DNA and panels of nuclear genes provides a noninvasive alternative to diagnosis. Specific criteria may assist in making a diagnosis (Table 105.4). Table 105.5

Clues to the Diagnosis of Mitochondrial Disease

Neurologic

Cerebral stroke-like lesions in a nonvascular pattern
Basal ganglia disease
Encephalopathy: recurrent or with low/moderate dosing of valproate

Neurodegeneration
Epilepsia partialis continua
Myoclonus
Ataxia
MRI findings consistent with Leigh disease
Characteristic MRS peaks
Lactate peak at 1.3 ppm TE (time to echo) at 35 and 135
Succinate peak at 2.4 ppm

Cardiovascular

Hypertrophic cardiomyopathy with rhythm disturbance
Unexplained heart block in a child
Cardiomyopathy with lactic acidosis (>5 mM)
Dilated cardiomyopathy with muscle weakness
Wolff-Parkinson-White arrhythmia

Ophthalmologic

Retinal degeneration with signs of night blindness, color vision deficits, decreased visual acuity, or pigmentary retinopathy
Ophthalmoplegia/paresis
Fluctuating, dysconjugate eye movements
Ptosis
Sudden- or insidious-onset optic neuropathy/atrophy

Gastroenterologic

Unexplained or valproate-induced liver failure
Severe dysmotility
Pseudoobstructive episodes

Other

A newborn, infant, or young child with unexplained hypotonia, weakness,

failure to thrive, and a metabolic acidosis (particularly lactic acidosis)
Exercise intolerance that is not in proportion to weakness
Hypersensitivity to general anesthesia
Episodes of acute rhabdomyolysis
Elevated GDF-15 level

MRI, Magnetic resonance imaging, MRS, magnetic resonance spectroscopy; GDF, growth and differentiation factor.

From Haas RH, Parikh S, Falk MJ, et al: Mitochondrial disease: a practical approach for primary care physicians, *Pediatrics* 120:1326–1333, 2007 (Table 1, p 1327).

The majority of mitochondrial disorders are caused by nuclear genes involved in mitochondrial function, and >300 genes have been included in nuclear gene panels for mitochondrial disorder diagnosis. However, pathogenic variants can be identified in 50% or fewer of patients diagnosed clinically with a mitochondrial disorder. An important consideration is that many genetic and multifactorial conditions have been associated with defects in 1 or more of the 4 complexes assayed in mitochondrial oxidative phosphorylation testing. These latter conditions feature so-called secondary mitochondrial dysfunction, because the conditions are not considered to be mitochondrial disorders per se.

Treatment remains largely symptomatic and does not significantly alter the outcome of disease. Some patients appear to respond to cofactor supplements, typically coenzyme Q_{10} ± L -carnitine at pharmacologic doses. The addition of creatine monohydrate and α-lipoic acid supplementation may add a significant benefit. EPI-743 is a parobenzoquinone like agent that has protective activity against oxidative injury; it is a promising agent in the treatment of mitochondrial disorders, including Leigh syndrome.

Leigh Disease (Subacute Necrotizing Encephalomyelopathy)

Leigh disease is a heterogeneous neurologic disease characterized by demyelination, gliosis, necrosis, relative neuronal sparing, and capillary proliferation in specific brain regions (see Chapter 616.2). Patients with Leigh disease frequently present with feeding and swallowing problems, failure to thrive, and developmental delay. The presentation is highly variable and may include seizures, altered consciousness, pericardial effusion, and dilated cardiomyopathy. **Diagnosis** is usually confirmed by radiologic or pathologic evidence of symmetric lesions affecting the basal ganglia, brainstem, and subthalamic nuclei. Patients with Leigh disease have defects in several enzyme complexes. Dysfunction in cytochrome-*c* oxidase (complex IV) is the most commonly reported defect, followed by NADH–coenzyme Q reductase (complex I), PDHC, and pyruvate carboxylase (see Chapter 106). Pathogenic variants in the nuclear *SURF1* gene, which encodes a factor involved in the biogenesis of cytochrome-*c* oxidase and mitochondrial DNA variants in the adenosine triphosphatase 6 coding region, have been reported in patients with Leigh disease in association with complex IV deficiency. The most common mitochondrial DNA variant in Leigh disease is the T8993G variant in *MT-ATP6* . The **prognosis** for Leigh syndrome is poor. In a study of 14 cases, there were 7 fatalities before age 1.5 yr.

Lactic acidosis, hypoglycemia, and encephalopathy have also been reported in patients with thiamine transporter deficiency and with pyridoxine-dependent epilepsy. Both disorders should improve by the provision of thiamine and pyridoxine, respectively.

Defects in Pentose Metabolism

Priya S. Kishnani, Yuan-Tsong Chen

Keywords

- hexose monophosphate
- pentosuria
- xylulose
- transaldolase
- ribose
- urine reducing substance

Approximately 90% of glucose metabolism in the body is via the glycolytic pathway, with the remaining 10% via the hexose monophosphate pathway. The hexose monophosphate shunt leads to formation of pentoses, as well as providing NADH. One of the metabolites is ribose-5-phosphate, which is used in the biosynthesis of ribonucleotides and deoxyribonucleotides. Through the transketolase and transaldolase reactions, the pentose phosphates can be converted back to fructose-6-phosphate and glucose-6-phosphate.

Essential Pentosuria

Essential pentosuria is a benign disorder encountered principally in Ashkenazi Jews and is an autosomal recessive trait. The urine contains **L -xylulose** , which is excreted in increased amounts because of a block in the conversion of L -xylulose to xylitol as a result of **xylitol dehydrogenase deficiency** . The condition is usually discovered accidentally in a urine test for reducing substances. No treatment is required.

Transaldolase Deficiency

Few patients have reported symptoms that include liver cirrhosis, hepatosplenomegaly, severe neonatal hepatopathy, and cardiomyopathy. Biochemical abnormalities revealed elevated levels of arabitol, ribitol, and erythritol in the urine. Erythronic acid has been identified by urine nuclear magnetic resonance spectroscopy as another hallmark metabolite. Enzyme assay in the lymphoblasts and fibroblasts demonstrated low transaldolase activity, which was confirmed by pathogenic variants in the transaldolase gene. In addition, measurement of transaldolase activity in fibroblasts, lymphoblasts, or liver tissue, as well as assessing urinary concentrations of polyols, also can be used to confirm the diagnosis.

Ribose-5-Phosphate Isomerase Deficiency

Only one case of this disorder has been reported. The affected male had psychomotor delay from early in life and developed epilepsy at 4 yr of age. Thereafter, a slow neurologic regression developed, with prominent cerebellar ataxia, some spasticity, optic atrophy, and a mild sensorimotor neuropathy. MRI of the brain at ages 11 and 14 yr showed extensive abnormalities of the cerebral white matter. Proton magnetic resonance spectroscopy (MRS) of the brain revealed elevated levels of ribitol and D -arabitol. These pentitols were also increased in urine and plasma similar to the patient found in transaldolase deficiency. Enzyme assays in cultured fibroblasts showed deficient **ribose-5-phosphate isomerase** activity, which was confirmed by a molecular study. These results, combined with a study of ribose-5-phosphate isomerase–deficient mice, demonstrated that the specific genetic pairing of a null allele with an allele coding for a form of the enzyme that is only partly active, allowing for cell type–dependent expression deficits, is a contributing factor to the rarity of the disease. Ribose-5-phosphate isomerase deficiency may represent an example of a single-gene disease that appears seldom because of its complex molecular etiology.

105.6

Disorders of Glycoprotein Degradation and Structure

Margaret M. McGovern, Robert J. Desnick

The disorders of glycoprotein degradation and structure include several lysosomal storage diseases that result from defects in glycoprotein degradation, and the congenital disorders of glycosylation (see Chapter 105.7). *Glycoproteins* are macromolecules composed of oligosaccharide chains linked to a peptide backbone. They are synthesized by 2 pathways: the glycosyltransferase pathway, which synthesizes oligosaccharides linked *O* -glycosidically to serine or threonine residues; and the dolichol, lipid-linked pathway, which synthesizes oligosaccharides linked *N* -glycosidically to asparagine.

The **glycoprotein lysosomal storage diseases** result from the deficiency of the enzymes that normally participate in the degradation of oligosaccharides and include sialidosis, galactosialidosis, aspartylglucosaminuria, and α-mannosidosis. In some instances the underlying abnormality that leads to glycoprotein accumulation also results in abnormal degradation of other classes of macromolecules that contain similar oligosaccharide linkages, such as certain glycolipids and proteoglycans. In these cases the underlying enzymatic deficiency results in the accumulation of both glycoproteins and *glycolipids*. The classification of these types of disorders as *lipidoses* or *glycoproteinoses* depends on the nature of the predominantly stored substance. In general, the glycoprotein disorders are characterized by autosomal recessive inheritance and a progressive disease course with clinical features that resemble those seen in the mucopolysaccharidoses.

Sialidosis and Galactosialidosis

Sialidosis is an autosomal recessive disorder that results from the primary deficiency of neuraminidase because of mutations in the gene (*NEU1*) that encodes this protein, located on chromosome 6p21.33. In contrast, **galactosialidosis** is caused by the deficiency of 2 lysosomal enzymes—neuraminidase and β-galactosidase. The loss of these enzymatic activities results from mutations in a single gene, *CTSA*, located on chromosome 20q13.12, that encodes the protective protein cathepsin A, which functions to stabilize these enzymatic activities. Neuraminidase normally cleaves terminal sialyl linkages of several oligosaccharides and glycoproteins. Its deficiency results in the accumulation of oligosaccharides, and the urinary excretion of sialic acid terminal oligosaccharides and sialylglycopeptides. Examination of tissues from affected individuals reveals pathologic storage of substrate in many tissues, including liver, bone marrow, and brain.

The clinical phenotype associated with neuraminidase deficiency is variable and includes **type I** sialidosis, which usually presents in the 2nd decade of life with myoclonus and cherry-red spots in the macula. These patients typically present secondary to gait disturbances, myoclonus, or visual complaints. In contrast, **type II** sialidosis occurs at several ages of onset (congenital, infantile, and juvenile), depending on the severity of the gene mutation. The **congenital** and **infantile** forms result from isolated neuraminidase deficiency, whereas the **juvenile** form results from both neuraminidase and β-galactosidase deficiency.

The congenital type II disease is characterized by hydrops fetalis, neonatal ascites, hepatosplenomegaly, stippling of the epiphyses, periosteal cloaking, and stillbirth or death in infancy. The type II infantile form presents in the 1st yr of life with dysostosis multiplex, moderate global developmental delays, visceromegaly, corneal clouding, cherry-red maculae, and seizures. The juvenile type II form of sialidosis, which is sometimes designated *galactosialidosis*, has a variable age of onset ranging from infancy to adulthood. In infancy, the phenotype is similar to that of GM_1 gangliosidosis, with edema, ascites, skeletal dysplasia, and cherry-red spots. Patients with later-onset disease have dysostosis multiplex, visceromegaly, intellectual disability, dysmorphism, corneal clouding, progressive neurologic deterioration, and cherry-red spots.

No specific therapy exists for any form of the disease, although studies in animal models have demonstrated improvement in the phenotype after bone marrow transplantation. The **diagnosis** of sialidosis and galactosialidosis is achieved by the demonstration of the specific enzymatic deficiency or by mutations in the responsible gene. **Prenatal diagnosis** using cultured amniotic cells or chorionic villi is available by demonstrating the enzyme defect and/or specific gene mutations.

Aspartylglucosaminuria

This is a rare autosomal recessive lysosomal storage disorder, except in Finland, where the carrier frequency is estimated at 1 in 36 adults, the high frequency due to a *founder* gene. The disorder results from the deficient activity of **aspartylglycosaminidase** and the subsequent accumulation of aspartylglycosamine, particularly in the liver, spleen, and thyroid. The gene for the enzyme *(AGA)* has been localized to chromosome 4q32-33, and the DNA and gene have been isolated and sequenced. In the Finnish population, a single *AGA* mutation encoding p.C163S accounts for most mutant alleles, whereas outside of Finland, a large number of private mutations have been described.

Affected individuals with aspartylglucosaminuria typically present in the 1st yr of life with recurrent infections, diarrhea, and umbilical hernias. Coarsening of the facies and short stature usually develop later. Other features include joint laxity, macroglossia, hoarse voice, crystal-like lens opacities, hypotonia, and spasticity. Psychomotor development is usually near normal until age 5 yr, when a decline is noted. Behavioral abnormalities are typically seen, and IQ values in affected adults are usually<40 (severe intellectual disability). Survival to adulthood is common, with most early deaths attributable to pneumonia or other pulmonary causes. Definitive **diagnosis** requires demonstration of markedly deficient aspartylglucosaminidase in peripheral blood leukocytes, and/or the specific *AGA* mutation(s). Several patients have undergone allogeneic bone marrow transplants, but this approach has not proved effective, and *no specific treatment is available*. **Prenatal diagnosis** is available by the determination of aspartylglucosaminidase deficiency and/or the specific *AGA* mutations in cultured amniocytes or chorionic villi.

α-Mannosidosis

This autosomal recessive disorder results from the deficient activity of **α-mannosidase** and the accumulation of mannose-rich compounds. The gene *MAN2B1* encoding the enzyme has been localized to chromosome 19p13.2-q12, and the cDNA and gene sequence have been determined. To date >140 gene mutations have been reported. Affected patients display clinical heterogeneity. There is a severe infantile form, or **type I** disease, and a milder juvenile variant, **type II** disease. All patients have psychomotor retardation, facial coarsening, and dysostosis multiplex. The **infantile** form of the disorder, however, is characterized by more rapid cognitive deterioration, with death occurring between ages 3 and 10 yr. Patients with the infantile form also have more severe skeletal involvement and hepatosplenomegaly. The **juvenile** disorder is characterized by onset of symptoms in early childhood or adolescence, with milder somatic features and survival to adulthood. Hearing loss, destructive synovitis, pancytopenia, and spastic paraplegia have been reported in type II patients. The **diagnosis** is made by the demonstration of the marked deficiency of α-mannosidase activity in white blood cells or cultured fibroblasts. Clinical trials of ERT with recombinant human α-mannosidase are underway. **Prenatal diagnosis** can be made by demonstrating the enzyme defect and/or the specific gene mutations in cultured amniocytes or chorionic villi.

Glycosylation is the complex multistep metabolic process of adding (oligo)saccharides to proteins and lipids. The classification of **disorders of hypoglycosylation** is based on biochemical structures: (1) defects in protein *N* -linked glycosylation, (2) defects in protein *O* -linked glycosylation, (3) defects in glycosphingolipid and in glycosylphosphatidylinositol-anchor glycosylation, and (4) defects in multiple glycosylation pathways and in other pathways (Fig. 105.7). No disorders are known to result from abnormal *C* -linked glycosylation. Congenital disorders of glycosylation are labeled based on their genetic defect *(CDG)* .

FIG. 105.7 Schematic of different types of glycosylation. ***Left to right,*** Glycosphingolipids, glycophospholipid anchor (GPI anchor), ***O*** -linked membrane protein glycosylation, ***N*** -linked membrane glycosylation, and secretory ***N*** -linked glycan.

Protein glycosylation is an essential pathway. Most functional proteins are glycosylated, including serum proteins (e.g., transferrin, ceruloplasmin, TBG), hormones (e.g., TSH, FSH, FH, ACTH, IGFBP3), and clotting and anticoagulation factors (e.g., factors IX and XI, antithrombin). Membrane proteins are also highly glycosylated. Important intracellular glycoproteins include enzymes such as glycosyltransferases or lysosomal enzymes.

N **-glycans** are linked to the amide group of asparagine. They are synthetized in a complicated process throughout the cytoplasm, endoplasmic reticulum (ER), and Golgi complex, starting with sugar activation and nucleotide sugar synthesis, then oligosaccharide assembly, and finally glycan processing (Fig. 105.8). The majority of the pediatric disorders are *N* -glycosylation disorders. ***O*** **-glycans** are linked to the hydroxyl group of serine or threonine. These diverse glycoproteins are mostly formed in the Golgi complex; their defects can involve xylosylation, fucosylation, mannosylation, or other modifications. An important focus is *O* -

mannosylation defects because of their relevance for dystroglycanopathies.

FIG. 105.8 **Overview of different cell compartments involved in *N* -linked protein glycosylation. Activation of nucleotide sugars in the cytoplasm is followed by step-by-step dolichol-linked synthesis of glycans associated with the endoplasmic reticulum. Transfer of the glycan from the lipid arm to the protein is followed by transport to the Golgi for further modifications.**

Lipid glycosylation is an essential process for the synthesis of ceramide and ganglioside synthesis. **Glycosylphosphatidylinositols** (GPIs) are very special glycolipids that link various proteins to the plasma membrane, as complex lipid-sugar anchors (GPI anchors, see Fig. 105.7).

Congenital disorders of glycosylation (CDG) are predominantly multisystem diseases, caused by >140 different genetic defects in glycoprotein and glycolipid glycan synthesis. This rapidly growing group is one of the newest and largest metabolic disorder groups. Most patients described with CDG have *N* -glycosylation defects, followed by the fastest-growing group of CDGs, involving multiple glycosylation pathways and dolicholphosphate synthesis. Smaller groups are *O* -glycosylation disorders and disorders of glycosylphosphatidylinositol. The “oldest” CDG is PMM2-CDG, in which the genetic defect leads to the loss of **phosphomannomutase 2** (PMM2), the enzyme that catalyzes the conversion of mannose-6-phosphate into mannose-1-phosphate. The majority of CDGs have an autosomal recessive inheritance. Only 2 *N* -linked CDGs are autosomal dominant, GANAB-CDG and PRKCSH-CDG. The dominantly inherited *O* -linked CDGs include EXT1/EXT2-CDG, POFUT1-CDG, and POGLUT1-CDG. X-linked CDGs include ALG13-CDG, SSR4-CDG, PIGA-CDG, SLC35A2-CDG, ATP6AP2-CDG and ATP6AP1-CDG.

Some CDGs are lethal; 20% of PMM2-CDG patients die in the 1st 2 yr of life. Some patients, however, stabilize throughout young adulthood. Almost any clinical phenotype can be present in a patient with CDG. It can affect any organ or organ system and most often includes the central nervous system (CNS). The most common clinical features include developmental and speech delay, seizures, ataxia, spasticity, peripheral neuropathy, hypotonia, strabismus, abnormal fat distribution, visual loss, cardiomyopathy, feeding difficulties, liver dysfunction, endocrine abnormalities, bleeding diathesis, and thrombosis (Fig. 105.9 and Table 105.6). Single-organ presentations are rare in CDGs (e.g., TUSC3-CDG and ST3GAL3-CDG: brain; DHDDS-CDG: retina; ALG14-CDG: neuromuscular junction; POFUT1-CDG and POGLUT1-CDG: skin; SEC23B-CDG: red cell lineage; EXT1/EXT2-CDG: cartilage; TMEM199-CDG: liver). Many CDGs are recognizable syndromes. CDG should be considered in any patient with a developmental disability or an unexplained clinical condition, especially in multisystem disease with neurologic involvement.

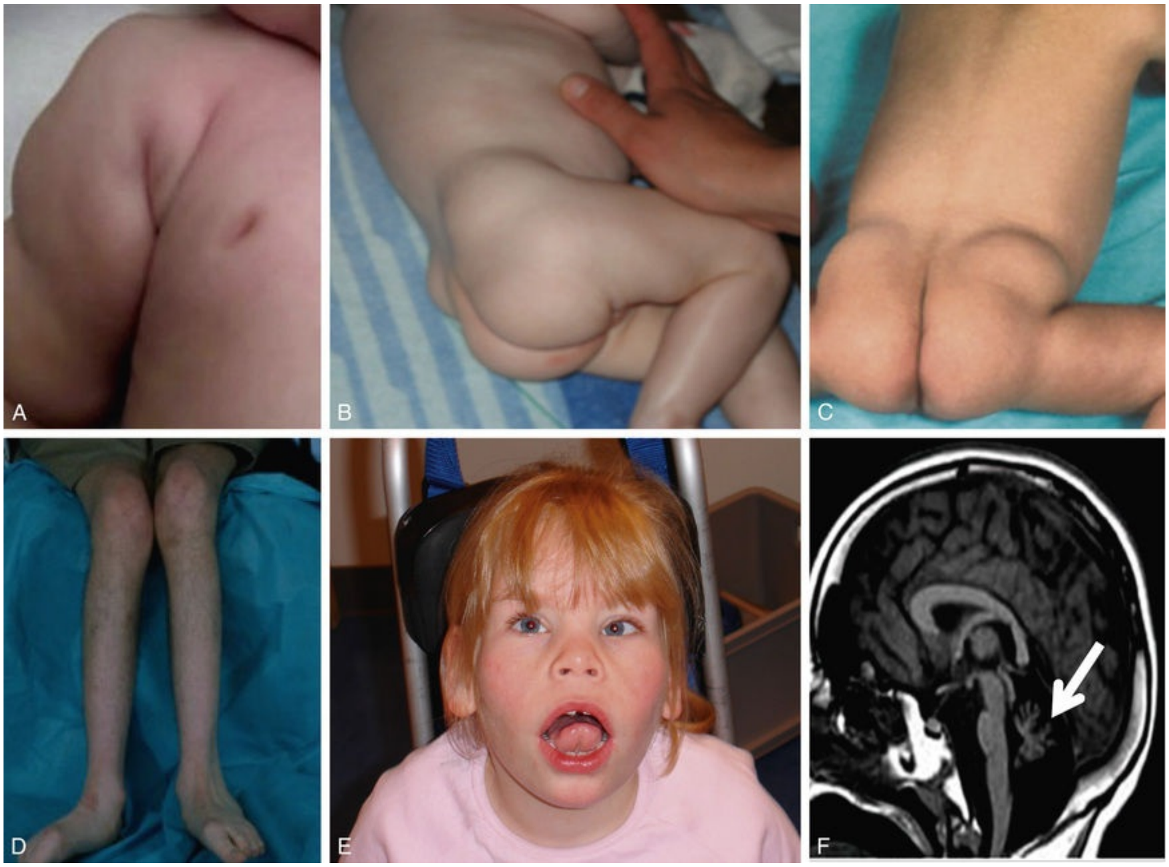

FIG. 105.9 Patients with phosphomannomutase-2 deficiency (PMM2-CDG) and recognizable clinical features. A, Inverted nipples. B and C, Abnormal fat distribution. D, Muscle atrophy caused by peripheral neuropathy after puberty. E, Characteristic facial features with strabismus, short nose, anteverted nares, long philtrum, and large ears. F, MRI of brain with T1-weighted sagittal image showing cerebellar vermis hypoplasia *(arrow)* and brain atrophy.

Table 105.6

Clinical and Laboratory Features in Common Congenital Disorders of Glycosylation (CDGs), with Clinically Recognizable Phenotype and Abnormal Glycosylation, Detectable by Serum Transferrin Isoform Analysis (TIEF)

DEFECTIVE GENE	MOST FREQUENT CLINICAL FEATURES	SUGGESTIVE FEATURES	LABORATORY ABNORMALITIES	OTHER BIOCHEMICAL ANOMALIES
PMM2	Strabismus, nystagmus, smooth philtrum, large ears, vomiting, diarrhea, FTT, axial hypotonia, cerebellar vermis hypoplasia, ataxia, psychomotor disability,	Inverted nipples and/or abnormal fat pads, stroke-like episodes	Elevated serum transaminases, hypoalbuminemia, decreased factor IX, XI and AT activity, low serum	Type 1 serum TIEF, decreased PMM activity in leukocytes and fibroblasts

	seizures, spasticity, neuropathy, pigmentary retinitis		ceruloplasmin and TBG levels	
PMI	Cholestasis, hepatomegaly, feeding difficulties, recurrent vomiting, chronic diarrhea, ascites, recurrent thrombosis, gastrointestinal bleeding	Hyperinsulinism, protein losing enteropathy Normal intelligence and absence of neurologic features	Elevated transaminases, hypoalbuminemia, hypoglycemia, decreased factor IX, XI, and AT-III activity	Type 1 serum TIEF, decreased PMI activity in leukocytes and fibroblasts
ALG6	Hypotonia, muscle weakness, seizures, ataxia, intellectual disability, behavioral abnormalities	(Distal limb malformations)	Elevated serum transaminases; hypoalbuminemia; decreased factor IX, XI, and AT activity; low serum IgG level	Type 1 serum TIEF, abnormal LLO results in fibroblasts
DPAGT1	Microcephaly, brain malformations, hypotonia, severe psychomotor disability, seizures, spasticity, proximal weakness, failure to thrive, joint contractures	Congenital myasthenia phenotype In multisystem phenotype: cataract	Decreased AT, protein C, and protein S activity; increased creatine kinase; hypoalbuminemia; normal creatine kinase in myasthenia	Type 1 serum TIEF
SRD5A3	Developmental delay, hypotonia, ataxia, cerebellar vermis hypoplasia, intellectual disability, speech delay, visual loss	Congenital cataract, retinal and iridic coloboma, glaucoma, optic nerve dysplasia, ichthyosis	Low anticoagulation factors (AT, protein C, and protein S activity), increased serum transaminases	Type 1 serum TIEF *but reported false-negative TIEF*
ATP6V0A2	Generalized cutis laxa, hypotonia, strabismus, characteristic facial features, joint laxity, seizures, motor and language developmental delay, spontaneous improvement of cutis laxa by aging	Cobblestone-like brain dysgenesis	Mild coagulation abnormalities, increased serum transaminase levels	Type 2 serum TIEF *but reported false-negative TIEF* Abnormal apoC-III IEF, characteristic MALDI TOF profile (Note abnormal skin histology)
ATP6V1A and ATP6V1E1		Cardiovascular anomalies	Mild coagulation abnormalities and increased serum transaminase levels, hypercholesterolemia	
PGM1	Pierre Robin sequence, cholestasis, short stature, dilated cardiomyopathy,	Cleft palate, hyperinsulinism, normal intelligence	Hypoglycemia, increased serum transaminase levels, decreased AT	Mixed type 1/ 2 serum TIEF, decreased fibroblast PGM1 activity
MAN1B1	Developmental delay, speech delay, intellectual disability, muscle weakness	Obesity, autistic features, inverted nipples, characteristic face	Increased serum transaminase levels, low AT	Type 2 serum TIEF, abnormal apoC-III IEF, diagnostic MALDI TOF profile
TMEM199	Cholestasis, hepatomegaly,	Normal intelligence	Decreased serum	Type 2 serum

CCDC115	liver steatosis, liver fibrosis, liver failure, spontaneous bleedings, motor developmental delay	Hepatomegaly	ceruloplasmin, increased serum transaminase levels, hypercholesterolemia, high AP	TIEF, abnormal apoC-III IEF, characteristic MALDI TOF profile
ATP6AP1 and ATP6AP2		Immune deficiency		
SLC39A8	Seizures, hypsarrhythmia, hypotonia, developmental and speech delay, FTT	Dwarfism, craniosynostosis, rhizomelia, Leigh disease	Decreased serum manganese, high serum transaminases, abnormal coagulation	Type 2 serum TIEF, abnormal apoC-III, characteristic MALDI TOF profile

AP, Alkaline phosphatase; AT, antithrombin; apoC-III: apolipoprotein C-III; FTT, failure to thrive; LLO, lipid-linked oligosaccharides; MALDI-TOF, matrix-assisted laser desorption/ionization time of flight; TBG, thyroxine-binding globulin; TIEF, transferrin isoelectric focusing.

There are also **congenital disorders of deglycosylation** , including known lysosomal disorders and a severe neurologic condition caused by defective *N* -glycanase function (*NGLY1* defect).

Laboratory evaluations in most *N* -linked CDGs rely on a primary screening method called serum **transferrin isoelectric focusing (TIEF)** . Transferrin isoforms, which are hyposialylated (missing terminal sialic acid residues), show different cathodal shifts depending on either missing glycan chains or truncated glycans. A **type 1 pattern** suggests an early metabolic defect in the cytosolic-ER–related glycan synthesis and assembly. A **type 2 pattern** suggests Golgi-related glycan-processing defects (Fig. 105.10).

FIG. 105.10 Diagnostic flow chart of glycosylation disorders affecting N-linked glycosylation. *Instead of TIEF, mass spectrometry methods can be used as well. IGFBP3, Insulin-like growth factor–binding protein 3; TBG, thyroxine-binding globulin; CDG, congenital disorders of glycosylation; PMM, phosphomannomutase; MPI, mannosephosphoisomerase, LLO, lipid-linked oligosaccharides; TIEF, transferrin isoelectric focusing; IEF, isoelectric focusing; MALDI-TOF, matrix-assisted laser desorption/ionization time of flight.

Isoelectric focusing of apolipoprotein C-III (**IEF apoC-III)** , a serum mucine type *O* -glycosylated protein, can detect some *O* -glycosylation disorders (combined *N* - and *O* -linked glycosylation defects). Mass spectrometry in serum for type 1 defects is highly sensitive for mild glycosylation abnormalities. Glycomics by matrix-assisted laser desorption/ionization time of flight (**MALDI-TOF**) can be diagnostic in specific types of CDG (mostly Golgi related with a type 2 pattern). Dolichol-linked glycan or lipid-linked oligosaccharide (LLO) analysis is a complicated but sensitive method to detect ER-related *N* -glycan assembly (CDG type 1) defects in patient fibroblasts. GPI-anchor defects can be suspected based on *recurrent elevation of alkaline phosphatase levels* in blood.

Dystroglycanopathies can be confirmed based on abnormal immunohistochemistry in muscle biopsy. Fluorescence-activated cell sorting (**FACS**) analysis of the membrane-anchored markers CD16 and CD24 in leukocytes is highly suggestive for a GPI-anchor abnormality, especially when alkaline phosphatase in blood is significantly elevated. Enzyme analysis in blood is only available for a few, more common CDGs (PMM2-CDG, MPI-CDG, PGM1-CDG); it is more reliable in fibroblasts.

With an abnormal TIEF pattern result or clinical suspicion of any type of CDG, most metabolic centers use a direct *CDG* gene panel analysis or next-generation sequencing (NGS; whole exome sequencing) (see Fig. 105.10).

Congenital Disorders of Protein *N* -Glycosylation

Phosphomannomutase-2 Deficiency (PMM2-CDG)

Clinical Manifestations

PMM2-CDG is the most common and easily recognizable CDG. Most patients have alternating strabismus, characteristic facial features (short nose, long philtrum, large ears) (Fig. 105.9*E*), inverted nipples and/or abnormal fat pads (Fig. 105.9*A* -*C*), feeding difficulties, axial hypotonia, and decreased reflexes, already in the 1st few mo of life. Nystagmus (caused by pontocerebellar and vermis hypoplasia; Fig. 105.9*F*) is also common. Psychomotor disability is present in most patients, but normal intellectual development has been described in a few patients. Most patients develop a multisystem disease, and <25% show an isolated neurologic phenotype without other organ involvement, normal endocrine regulation, and no coagulopathy. The neurologic involvement is quite diverse, with ataxia, seizures, spasticity, and peripheral neuropathy (Fig. 105.9*D*) the most common features. Dystonia, stroke-like episodes, and proximal myopathy can also occur. PMM2-CDG is not a progressive disease, but certain features, when present, typically appear at different ages during the disease. From birth, pericardial fluid collection, cardiomyopathy, or chronic vomiting/diarrhea can occur; after 7 yr, retinitis pigmentosa and cataract; and after puberty, scoliosis, neuropathy, and recurrent thrombotic events. Liver function anomalies are mild, and only a few patients develop cholestasis or liver fibrosis. Most patients have a hypergonadotropic hypogonadism; no successful pregnancies have been reported. Intellectual disability can be mild to severe; speech development is frequently delayed and can even be absent. Autistic behavior is common, although patients usually have a cheerful personality.

Pathophysiology

Phosphomannomutase 2 catalyzes the conversion of mannose-6-phosphate to mannose-1-phosphate, essential for the formation of activated mannose units used in the synthesis of the growing glycan chain in the ER. Hypoglycosylation leads to abnormal function affecting many essential glycoproteins, such as coagulation and anticoagulation factors, endocrine regulation, transport proteins, liver function, and immune, membrane, and receptor proteins.

Diagnosis

The primary screening method for PMM2-CDG is serum transferrin glycoform analysis, which is most frequently performed by TIEF. Intact transferrin has 4 negatively charged sialic acid residues (tetrasialotransferrin). Transferrin glycoforms, missing terminal sialic acid residues, show different cathodal shifts, less abundant tetrasialotransferrin, increased disialotransferrin, and some a-sialotransferrin (see Fig. 105.10). This is the so-called type 1 pattern, suggestive of a defect in glycan assembly in the cytosol-ER. Transferrin isoforms are also detectable by mass spectrometry. Certain other disorders can cause a *false-positive* transferrin isoform pattern, including galactosemia, hereditary fructose intolerance, and excessive alcohol use. PMM enzyme analysis is available in leukocytes and fibroblasts.

The presence of elevated serum transaminases, hypoalbuminemia, decreased factor IX and XI and antithrombin activity, or low ceruloplasmin or thyroxine-binding globulin (TBG) level is highly suggestive of CDG, including the most common type, PMM2-CDG.

PMM2-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The most frequent pathogenic variant (c.422G>A; R141H) is present in 75% of patients of Caucasian origin. The exact incidence of PMM2-CDG is not known, but it is estimated to be as high as 1 in 40,000-80,000 in Europe. Prenatal diagnosis is only reliable by genetic testing.

Treatment

The therapy in PMM2-CDG relies on supportive treatment. Even with the best treatment, mortality is about 20% in the 1st 2 yr of life, mostly from cardiac or kidney involvement and severe infections. Current recommended therapy includes adequate nutrition, diet or tube feeding if needed, cardiac support, hormone supplements, physical and occupational therapy, speech therapy, seizure management, and strabismus surgery. Therapeutic developments include targeted mannose-phosphate treatment, and chaperone therapy; these are only in preclinical trial phases.

Mannosephosphoisomerase Deficiency (MPI-CDG)

Clinical Manifestations

MPI deficiency is a recognizable and treatable CDG. Most patients show early symptoms of liver disease (cholestasis, elevated transaminases) and feeding difficulties, with recurrent vomiting and chronic diarrhea, most frequently with protein-losing enteropathy. Life-threatening episodes might appear as early as the 1st few mo of life with recurrent thrombosis and severe gastrointestinal bleeding because of severe coagulation abnormalities. Hypoglycemia is usually caused by hyperinsulinism. Hypoalbuminemia can be severe; patients might develop visible abdominal distention from a combination of ascites and hepatomegaly. Patients with MPI-CDG have no other organ involvement, and the CNS is not affected. There are no dysmorphic features. The liver disease frequently progresses to fibrosis or cirrhosis.

Pathophysiology

Mannosephosphoisomerase (MPI) catalyzes the conversion of fructose-6-phosphate to mannose-6-phosphate, 1 step before PMM2, therefore blocking the formation of activated mannose units (GDP mannose) for oligosaccharide synthesis. Hypoglycosylation leads to abnormal glycoprotein function the same as in PMM2-CDG, especially coagulation and anticoagulation factors, liver function, and hormone receptors.

Diagnosis

The primary screening method in a suspected MPI-CDG patient is serum transferrin isoform analysis by TIEF (see Fig. 105.10) or MS analysis. MPI deficiency leads to a type 1 pattern, as seen in PMM2 deficiency. MPI enzyme analysis is available in leukocytes and fibroblasts. The presence of elevated serum transaminases, hypoalbuminemia, decreased factor IX and XI and antithrombin activity, hyperinsulinism, and nonketotic hypoglycemia are highly suggestive for MPI-CDG.

MPI-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence of MPI-CDG is not known, but it is estimated at 1 : 800 000 in Europe. Prenatal diagnosis is only reliable by genetic testing. Although this is a rare CDG, early diagnosis is imperative because it is treatable.

Treatment

MPI-CDG is the first CDG type treatable by dietary therapy. Mannose therapy is clinically effective by both IV and oral supplementation of 1 g/kg/day divided into 3-4 doses. A known side effect is hemolysis. The treatment uses an alternative pathway: mannose can be phosphorylated by hexokinases to mannose 6-phosphate, bypassing the MPI defect. The clinical symptoms improve rapidly, but liver function might further deteriorate. Liver fibrosis and cirrhosis might necessitate liver transplantation, which will resolve the metabolic disease. The oldest patient known with MPI-CDG has survived into her late 30s.

Glucosyltransferase-1 Deficiency (ALG6-CDG)

Clinical Manifestations

ALG6-CDG is the 2nd most common CDG. Most patients have hypotonia, muscle weakness, seizures, and ataxia. To date, no patient with ALG6-CDG has normal intelligence. Speech delay and nystagmus are common neurologic signs. Brachydactyly, skeletal abnormalities, and transverse limb defects have been observed. Strabismus and characteristic facial dysmorphism are rare (hypertelorism, oval face, short nose). Inverted nipples and/or abnormal fat pads are exceptional in ALG6-CDG.

The most severe ALG6-CDG patients show a multisystem phenotype in the 1st few mo of life, including severe infections, protein-losing enteropathy, hypoalbuminemia, anemia, and failure to thrive. Autistic behavior and mood changes have been observed in several patients. The oldest patient to date is almost 45 yr.

Pathophysiology

The metabolic problem is caused by defective binding of the 1st of 3 glucoses to the lipid-linked oligosaccharide in the ER. This glucose binding is essential for attachment of the oligosaccharyltransferase enzyme complex to the newly built oligosaccharide chain and the ability to transfer it to the protein. This leads to protein hypoglycosylation and abnormal glycoprotein function similar to PMM2-CDG and MPI-CDG. Laboratory abnormalities are also similar, including abnormalities in coagulation and anticoagulation factors, liver function, thyroid hormones, and immunoglobulins (IgG).

Diagnosis

The primary screening method in a suspected ALG6-CDG patient is serum transferrin glycoform analysis by TIEF or MS analysis. ALG6 deficiency leads to a type 1 pattern (see Fig. 105.10), as seen in PMM2 and MPI deficiency. There is no available enzyme analysis, although lipid-linked oligosaccharides could be evaluated in patient fibroblasts.

ALG6-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The most common mutations are p.A333V and p.I299Del. Prenatal diagnosis is only reliable by genetic testing. The exact incidence of ALG6-CDG is not known.

Treatment

The current therapy in ALG6-CDG relies on supportive treatment. Mortality is about 10% in the 1st years of life, mostly from protein-losing enteropathy and severe infections.

UDP-GlcNAc:Dol-P-GlcNAc-P Transferase Deficiency (DPAGT1-CDG)

Clinical Manifestations

DPAGT1 deficiency is a recognizable and potentially treatable CDG. About one third of patients show the **congenital myasthenia** phenotype, indistinguishable from other genetic congenital myasthenias. Creatine kinase (CK) levels are normal. These patients have a relatively good prognosis, especially with early myasthenia therapy. The other patients show a multisystem phenotype with microcephaly, brain malformations, hypotonia, severe psychomotor disability, seizures, spasticity, failure to thrive, joint contractures, and cataracts.

Pathophysiology

DPAGT1 defect leads to very early arrest of glycan synthesis outside the ER membrane, by slowing down the addition of the 2nd GlcNAc sugar to the phosphorylated dolichol arm. Abnormal receptor glycosylation in the *neuromuscular junction* leads to myasthenia. Hypoglycosylation in the multisystem type leads to abnormal glycoprotein function similar to that in PMM2-CDG, especially involving the anticoagulation factors, and interestingly leading to high serum CK (in contrast to the congenital myasthenia phenotype) and hypoalbuminemia.

Diagnosis

The primary screening method is serum transferrin glycoform analysis or MS analysis. Most patients show a type 1 pattern (see Fig. 105.10), but patients with the congenital myasthenia phenotype can show normal screening. There is no clinically available enzyme analysis.

DPAGT1-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence is not known. Prenatal diagnosis is only reliable by genetic testing. Because of the false-negative TIEF results in several patients with the myasthenic phenotype, congenital myasthenia panel testing is suggested in suspected cases, especially for determining the potential therapy.

Treatment

The congenital myasthenia phenotype is frequently treatable by high-dose pyridostigmine, eventually enhanced with salbutamol. In the multisystem phenotype of DPAGT1-CDG, treatment is supportive.

Congenital Disorders of Protein *O* -Glycosylation

Cerebro-Ocular Dysplasia–Muscular Dystrophy and Muscle-Eye-Brain Disease

Spectrum (POMT1-CDG, POMT2-CDG, POMGNT1-CDG)

From isolated muscular dystrophy to **Walker Warburg syndrome** , this group of *O* -linked glycosylation disorders presents with severe muscle weakness, congenital eye malformations, and neuronal migration defects. Pachygyria, cobblestone dysgenesis, hydrocephalus, polymicrogyria, heterotopias, and corpus callosum agenesis are variably present. Eye malformations include anophthalmia, microphthalmia, congenital cataract, or colobomas. **Congenital muscular dystrophy** is associated with significant CK level elevations. There is severe psychomotor disability.

The underlying metabolic defect is the abnormal synthesis of the *O*-mannosylglycan core, which is essential for the proper glycosylation of α-dystroglycan. The α-dystroglycan is heavily *O* -glycosylated with mannose residues and is expressed in both muscle and brain. Defective mannosylation of α-dystroglycan leads to muscle degeneration and migration defects. Muscle biopsy shows abnormal α-dystroglycan staining on immunohistochemistry.

Transferrin isoelectric focusing is normal in patients with isolated *O* -mannosylation defects. There is also no clinically available enzyme analysis. **Diagnosis** is based on histology (muscle biopsy) and genetic analysis.

POMT1-CDG, POMT2-CDG, POMGNT1-CDG are the most common autosomal recessive α-dystroglycanopathies. Additional gene defects occur in the pathway; *POMK*, *FKTN*, *FKRP*, *LARGE*, *B4GAT1*, *TMEM5*, and *ISPD* have been described in association with human disease. The exact incidence of α-dystroglycanopathies is not known.

In α-dystroglycanopathies the **treatment** is supportive.

Defects in Lipid Glycosylation and in Glycosylphosphatidylinositol Anchor Biosynthesis

Hyperphosphatasia–Intellectual Disability Syndromes: PIGA Deficiency (PIGA-CDG)

This clinically recognizable syndrome is an epilepsy syndrome with intellectual disability, hypotonia, dysmorphic facial features, skin anomalies, congenital brain malformations, and behavioral abnormalities, including autism. Other organ malformations, including cardiac and renal defects, have also been reported. (Note that *somatic* mutations with *PIGA* defect can also lead to paroxysmal nocturnal hemoglobinuria.)

N -acetylglucosamine (GlcNAc) cannot be efficiently transferred to phosphatidylinositol for glycophosphatidylinositol synthesis. Abnormal anchoring of alkaline phosphatase leads to hyperphosphatasemia in blood and loss of specific surface antigens on blood cells.

Transferrin isoform analysis is normal in GPI-anchor defects. FACS analysis of the membrane-anchored markers CD16 and CD24 in leukocytes is highly suggestive for a GPI-anchor abnormality, especially in association with increased levels of serum alkaline phosphatase. Mutation analysis confirms the defect.

PIGA-CDG is X-linked. The exact incidence is not known. A similar phenotype has been described in *PIGO, PIGV, PIGY, PIG*, *PGAP2*, and *PGAP3* defects.

In PIGA-CDG the **treatment** is supportive.

Defects in Multiple Glycosylation Pathways and in Other Pathways, Including Dolicholphosphate Biosynthesis Defects

Steroid 5α-Reductase Deficiency (SRD5A3-CDG)

Clinical Manifestations

SRD5A3 deficiency is a clinically recognizable CDG, originally described as a multiple–congenital malformation syndrome. About 20 patients have been diagnosed at different ages, including one at 45 yr. Patients have hypotonia, ataxia, and eye abnormalities, including congenital cataract, retinal and iridic colobomas, glaucoma, optic nerve dysplasia, and visual loss. Cerebellar vermis hypoplasia can be variable. Intellectual disability has been described in all affected patients thus far. About one third of patients have severe *congenital ichthyosis* . Hypertrichosis and dysmorphic facial features are common, including squared face, high forehead, large ears, and coarsening. Some children with SRD5A3-CDG have a severe autism spectrum disorder. Skeletal abnormalities (scoliosis) and cardiac malformations are less common.

Pathophysiology

SRD5A3 deficiency leads to abnormal dolichol synthesis affecting early glycan synthesis outside the ER membrane and affects *O* -mannosylation and GPI-anchor synthesis. Hypoglycosylation affects anticoagulation factors and leads to increased serum transaminases.

Diagnosis

The primary screening method in a suspected SRD5A3-CDG patient is serum transferrin glycoform analysis or MS analysis. Most patients show a type 1 pattern (see Fig. 105.10), but several false-negative cases have been described. There is no clinically available enzyme analysis.

SRD5A3-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence is not known.

Treatment

In SRD5A3-CDG the treatment is supportive.

Autosomal Recessive Cutis Laxa Type 2 (ARCL-2A or ATP6V0A2-CDG, ATP6V1A-CDG and ATP6V1E1-CDG)

Clinical Manifestations

ATP6V02-CDG is a multiple-malformation syndrome originally described as *cutis laxa syndrome* and recently discovered to be a combined *N* - and *O* -linked glycosylation disorder. Patients show generalized cutis laxa with inelastic, sagging skin at birth, hypotonia, strabismus, myopia, characteristic facial features, and joint laxity. The facial features include hypertelorism, short nose, long philtrum, down-slanting palpebral fissures with sagging eyelids, and sagging cheeks. Cardiovascular involvement is rare, and there is variable CNS involvement. Seizures and motor and language developmental disability are common, but normal intelligence has been described as well. Sensorineural hearing loss is sometimes observed. Some patients have vermis hypoplasia, and several children have been described with cobblestone like dysgenesis and partial pachygyria on brain MRI. Skeletal abnormalities and short stature are common, as well as late-closing fontanels, and/or brachydactyly and scoliosis. There is frequently enamel dysplasia. The skin features spontaneously improve with age. **ATP6V1A-CDG** and **ATP6V1E1-CDG** show a highly overlapping phenotype with associated cardiovascular symptoms and hypercholesterolemia.

Pathophysiology

ATP6V0A2 is a membrane subunit of the proton pump of the vesicular adenosine triphosphatase (V-ATPase) complex. Abnormal function of the V-ATPase complex alters the pH gradient in the secretory pathway and affects the maturation and transport of several glycosyltransferases and elastic fibers (e.g., elastin). ATP6V1A and ATP6V1E1 are other complex subunits affecting ATP6V0A2 function and cause secondary ATPase deficiency. Both *N* - and *O* -linked glycosylation are affected. There are mild coagulation abnormalities and high serum transaminase levels in some patients.

Diagnosis

The primary screening method in a suspected ATP6V0A2-CDG patient is serum transferrin glycoform analysis or MS analysis. Most patients show a type 2 pattern (see Fig. 105.10), but false-negative cases have been described before age 6 wk. Apolipoprotein III-C (apoC-III) is a mucin-type secretory glycoprotein that is only *O* -glycosylated. ApoC-III IEF shows a hypoglycosylation pattern in patients, even when the TIEF is falsely negative. Skin biopsy in patients show classic histologic changes of cutis laxa with diminished, short, abnormal, and fuzzy elastic fibers.

ATP6V0A2-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence is not known. *ATP6V1A* and *ATP6V1E1* defects have been recently described.

Treatment

In autosomal recessive cutis laxa type 2, the treatment is supportive. There is continuous and spontaneous improvement of skin symptoms throughout the disease course, especially in ATP6V0A2-CDG.

Golgi-$\alpha_{1\text{-}2}$ Mannosidase-1 Deficiency (MAN1B1-CDG)

Clinical Manifestations

MAN1B1 defect was originally described as an intellectual disability syndrome in association with dysmorphic features. Additional patients were recognized with psychomotor disability, muscle hypotonia, and inverted nipples in association with truncal obesity. The degree of intellectual disability is quite variable. Autistic behaviors, eating disorders, and aggressive behavior are frequent features. More than 30 patients have been reported.

Pathophysiology

MAN1B1 codes for a Golgi mannosidase, which is essential for the final “trimming” of mannose units during the glycan processing in the Golgi. Hypermannosylation leads to abnormal, truncated glycans and CDG-II. The glycosylation abnormality in serum is relatively mild. Increased serum transaminases and abnormal coagulation are uncommon.

Diagnosis

Most patients show a mild type 2 pattern by TIEF, but false-negative cases have been described. MALDI-TOF analysis shows characteristic, hybrid glycans in serum. In suspected cases, direct sequence analysis is recommended, even if the TIEF is normal.

MAN1B1-CDG is autosomal recessive. The exact incidence is unknown; several adult patients are known.

Treatment

Only supportive treatment is available.

Phosphoglucomutase-1 Deficiency (PGM1-CDG)

Clinical Manifestations

PGM1-CDG is a disorder presenting with midline malformations (cleft palate, Pierre Robin sequence, bifid uvula), liver dysfunction, hypoglycemia, and short stature in almost all patients. *Hypoglycemia* is usually caused by hyperinsulinism in the 1st years of life. It can resolve with aging; ketotic hypoglycemia has also been observed. Cholestasis, liver fibrosis, and even cirrhosis have been described in a few patients. About one third of patients also show proximal muscle weakness and dilated cardiomyopathy; the latter led to mortality in at least 7 reported cases. Other malformations, including cardiac and skeletal anomalies, have also been described. Wound healing is frequently abnormal, and there is a very high risk for bleeding during surgery. Intelligence is normal.

Pathophysiology

Phosphoglucomutase 1 (PGM1) is an essential enzyme for glycogenolysis and glycolysis. It also provides substrates for nucleotide sugars needed for normal glycosylation. PGM1 regulates the bidirectional conversion of glucose-1-phosphate and glucose-6-phosphate. During fasting it leads to a glycogenosis-like phenotype (also called GSD XIV, MIM 614921). PGM1-CDG affects both the ER- and Golgi-related glycosylation and causes a mixed type 1/type 2 hypoglycosylation pattern. Abnormal serum proteins include coagulation and anticoagulation factors, insulin-like growth factor–binding protein 3 (IGFBP3), TBG, and thyroid-stimulating hormone (TSH), in addition to serum transaminases, hypoglycemia, and elevated CK.

Diagnosis

The primary screening method in a suspected PGM1-CDG is serum transferrin glycoform analysis or MS analysis. Patients show a mixed type 1/type 2 pattern.

PGM1-CDG is autosomal recessive. It is among the relatively common CDGs; >40 patients have been described. Enzyme testing is possible in blood, but is more reliable in fibroblasts. Direct sequencing is available for testing.

Treatment

PGM1-CDG seems to be the 2nd treatable CDG besides MPI-CDG. D-Galactose is hypothesized to restore the balance in the availability of different nucleotide sugars. Adding 1 g/kg/day D-galactose for a few weeks to the diet improves glycosylation significantly, although the TIEF pattern does not fully normalize. This treatment improves liver transaminases and antithrombin levels and in some patients the hormonal status. The effect of D-galactose on hypoglycemic episodes and the myopathy is not yet clear. Larger, long-term dietary trials are ongoing.

Disorders of Golgi Homeostasis: TMEM199-, CCDC115-, ATP6AP2-CDG, and ATP6AP1-CDG

Clinical Manifestations

These 4 disorders are clinically and biochemically indistinguishable. They have been described with liver function anomalies, cholestasis, fibrosis, and cirrhosis with liver failure, necessitating liver transplantation in a few patients. The phenotype resembles **Wilson disease** , especially because of low serum ceruloplasmin and copper levels, but there is no Kayser-Fleischer ring. In CCDC115-CDG there are frequently also neurologic features. The intellectual outcome is variable. Additional abnormalities include hypercholesterolemia and elevated alkaline phosphatase. In ATP6AP1-CDG there is also immunologic involvement.

Pathophysiology

TMEM199-, CCDC115-, ATP6AP1-CDG, and ATP6AP2-CDG are important for Golgi homeostasis. The exact pathologic mechanism is not yet known, but it is hypothesized that the secondary Golgi dysfunction affects and delays the normal glycosylation process.

Diagnosis

The primary screening method in a patient with suspected PGM1-CDG is serum transferrin glycoform analysis or MS analysis. Patients show a type 2 pattern (see Fig. 105.10). ApoC-III IEF is abnormal. Glycomics results by MALDI-TOF analysis are characteristic but cannot discriminate between the 3 defects. Final diagnosis requires mutation analysis.

TMEM199-CDG and CCDC115-CDG are autosomal recessive, whereas ATP6AP1-CDG, and ATP6AP2-CDG are X-linked.

Treatment

Treatment is supportive; 2 patients successfully underwent liver transplantation.

Manganese Transporter Defect: SLC39A8-CDG

Clinical Manifestations

This intriguing disorder was originally described as a neurologic disease with hypotonia, seizures (hypsarrhythmia), and developmental disability. Some of the later-described patients had severe *skeletal dysplasia* with rhizomelic chondrodysplasia, craniosynostosis, and dwarfism. Mitochondrial dysfunction (Leigh disease, cerebral lactic acidemia, dystonia) may also be present.

Pathophysiology

SLC39A8 is a membrane transporter, responsible for the manganese (Mn) transmembrane transport. SLC39A8 deficiency affects all Mn-dependent enzymes and therefore different parts of the metabolism. Since several glycosyltransferases (e.g. β-1,4-galactosyltransferase) are Mn dependent, a secondary Golgi glycosylation occurs with a type 2 glycosylation defect. Low serum Mn levels are suggestive but not always present in patients.

Diagnosis

The primary screening method in a suspected SLC39A8-CDG is serum transferrin glycoform analysis or MS analysis. Patients show a type 2 pattern (see Fig. 105.10). MALDI-TOF analysis is suggestive, but not discriminative. Final diagnosis requires mutation analysis.

SLC39A8-CDG is an autosomal recessive disease. Its incidence is unknown.

Treatment

Besides supportive treatment, a few patients showed biochemical and clinical improvement (better seizure control) with oral D -galactose (1-3 g/kg/day) therapy.

Congenital Disorders of Deglycosylation

N-Glycanase 1 Deficiency (*NGLY1* Defect)

Clinical Manifestations

Patients with NGLY1 deficiency do have a glycosylation disorder, but not from the deficient synthesis; rather, it is caused by deficient breakdown of glycoproteins. The phenotype comprises severe CNS involvement, microcephaly, intellectual disability, seizures, neuropathy, movement disorders, and hypotonia. The presence of *alacrimia* , hypolacrimia, or chalazion is highly suggestive for the diagnosis, but not all patients have problems with tearing. Other features include failure to thrive, intrauterine growth restriction, and liver involvement. Some patients have a recognizable oval face with a short nose, flat profile, and hypertelorism. Masklike face also occurs, imitating the phenotype of mitochondrial disorders, especially when serum lactic acid levels are also elevated.

Pathophysiology

N -glycanase is responsible for the deglycosylation of misfolded *N* -linked glycoproteins. The enzyme is essential for cutting off the glycans before the proteins are degraded in the ER. The increased abundance of misfolded *N* -glycans increases ER stress, which has been suggested as a possible reason for lactate elevation in several patients. Serum transaminase and α-fetoprotein levels are also frequently increased.

Diagnosis

Serum transferrin isoform analysis shows a normal pattern. Final diagnosis requires mutation analysis.

NGLY1-CDG is an autosomal recessive disease. The most common mutation is c.1201A>T/p.R401X. The exact incidence of the condition is unknown, but >20 patients have been reported in a few years since the discovery of the disease.

Treatment

Only supportive treatment is available for the patient with NGLY1 deficiency.

Therapeutic Summary

Most CDGs are only treatable with supportive therapy. The initially discovered oral mannose treatment in MPI-CDG (1 g/kg/day) has proved to be efficient for coagulation problems and protein-losing enteropathy but cannot prevent liver fibrosis in all patients. Liver transplantation in MPI-CDG has been successful in a few patients. Oral D-galactose in PGM1-CDG (1g/kg/day) improves serum transaminases and coagulation, and has a positive effect on endocrine function, but cannot restore glycosylation fully. Seizure frequency improved in patients with SLC39A8-CDG receiving oral D -galactose treatment (1 g/kg/day) and oral Mn intake. The congenital myasthenic syndrome in DPAGT1-CDG, GFPT1-CDG and GMPPB-CDG has been successfully treated with high dose of cholinesterase inhibitors. Several CDG have been positively controlled by transplantation; including DOLK-CDG (DK1-CDG; heart transplantation) PGM3-CDG (hematopoietic stem cell transplantation), CCDC155-CDG (liver transplantation).

Additional CDG treatment options are available for disorders not described in this chapter. Patients with CAD-CDG show significant clinical improvement on receiving oral uridine therapy, especially with seizure control. Two children with SLC35C1-CDG–defective immune function improved on oral fucose therapy. GNE-CDG patients showed significant improvement in muscle strength on *N* -acetylmannoseamin therapy. Several dietary trials are currently ongoing in different CDG.

CHAPTER 106

Mitochondrial Disease Diagnosis

Marni J. Falk

See also Chapter 105.4 .

Overview of Mitochondrial Disease

Mitochondrial diseases are multisystemic energy failure states with extensive clinical and genetic heterogeneity. Their common basis is best understood through recognition that mitochondria function as biologic “fuel cells” or “batteries,” producing chemical energy in the form of adenosine triphosphate (ATP) by aerobic metabolism of nutrient-derived reducing equivalents, through the integrated function of the 5-complex mitochondrial **respiratory chain (RC)** (Fig. 106.1). Mitochondria also play other essential roles that can be variably disrupted in disease states, such as regulating calcium homeostasis, diverse aspects of intermediary nutrient metabolism, nucleotide metabolism, and oxidative stress. Primary mitochondrial disease results from deficient RC function, which can be caused by mutations in genes that encode RC subunits, assembly factors or cofactors, components of mitochondrial DNA (mtDNA) metabolism and maintenance, or a host of other basic metabolic processes ongoing within mitochondria. Approximately 1,500 proteins exist within the mitochondrial proteome of different tissues, with variants in more than 350 unique genes across both the nuclear and the mitochondrial genomes already implicated as causal in human mitochondrial disease.

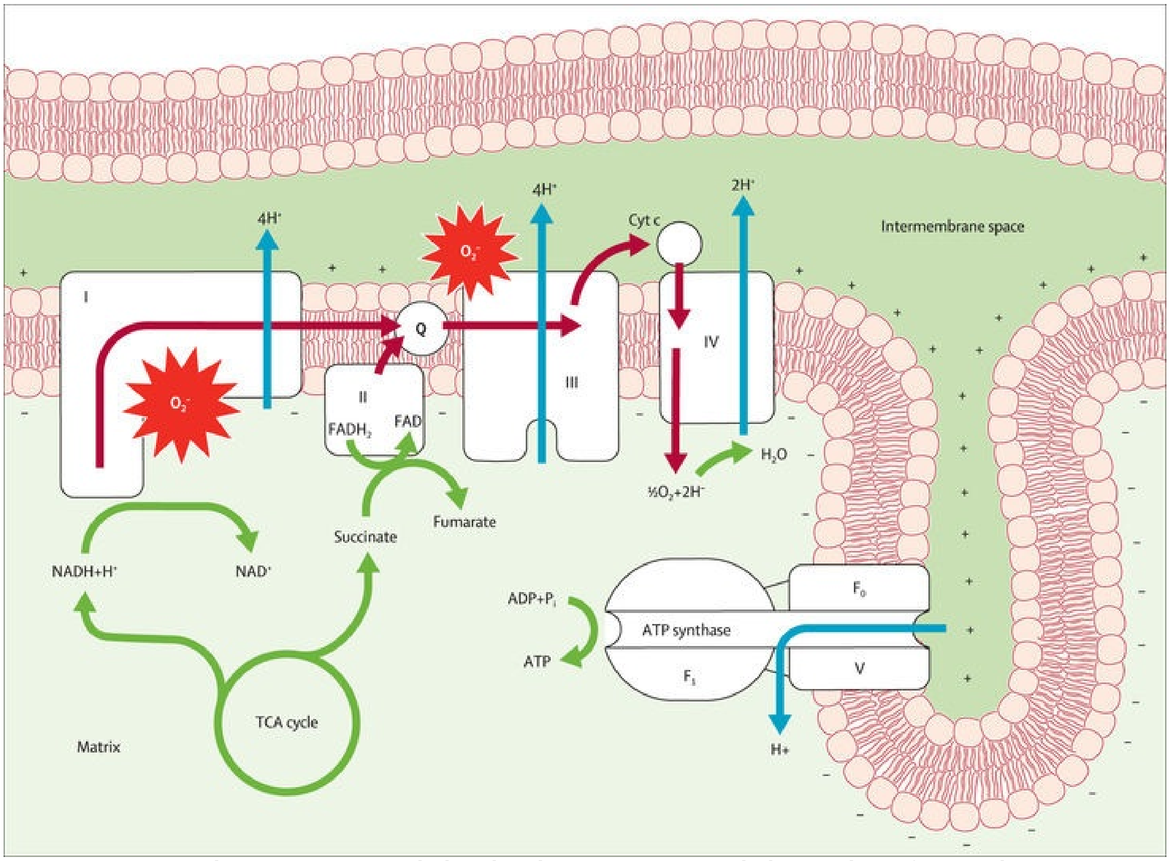

FIG. 106.1 **Electron transport chain. The electron transport chain consists of 4 protein complexes (I-IV) coupled to a 5th (V), unlinked complex, ATP synthase. Together, these 5 complexes are known as the respiratory chain and are the site where oxidative phosporylation (OXPHOS) occurs to generate energy. The transport chain accepts electrons from NADH (complex I) or $FADH_2$ (complex II) that have been produced by glycolysis, the formation of acetyl–coenzyme A, and the TCA cycle *(green arrows).* Electrons flow from one complex to another *(red arrows)* because of the redox potential of each complex and lose a small amount of energy as they move through the chain. Three of the 4 complexes act as pumps, driven by electron flow, moving H^+ ions from the matrix to the intermembrane space *(blue arrows)* . This pumping builds a concentration gradient and creates an electrochemical force that is used by ATP synthase to produce ATP. Under normal conditions, this machinery provides almost all (90%) of the ATP in a cell. However, a small proportion of electrons escape the electron transport chain even under normal conditions and can react with oxygen and complexes I and III to form superoxide ($O_2{}^-$). ADP, Adenosine diphosphate; ATP, adenosine triphosphate; Cyt c, cytochrome *c* ; Q, coenzyme Q; NADH, nicotinamide dinucleotide; Pi, inorganic phosphate; TCA, tricarboxylic acid cycle; FADH2, 1,5-dihydro-flavin adenine dinucleotide. (Adapted from Hagberg H, Mallard C, Rousset CI, Thornton C: Mitochondria: hub of injury responses in the developing brain, *Lancet Neurol* 13(2):217–232, 2014.)**

Collectively recognized as the most common group of inherited metabolic diseases, **primary** (genetic-based) mitochondrial disease has a combined minimal prevalence of 1 in 4,300 individuals across all ages. In addition, **secondary** mitochondrial dysfunction is broadly implicated in the pathogenesis of a host of complex diseases, ranging from metabolic syndrome to ischemia-reperfusion injury after stroke, to neurodegenerative diseases. Failure of high-energy demand organs in mitochondrial diseases may clinically present as severe neurodevelopmental, cardiac, myopathic, renal, hepatic, endocrine, immune, gastrointestinal, hearing, and vision disabilities, as well as global metabolic instability with lactic acidosis (Fig. 106.2) (see Tables 105.2 and 105.3). In most mitochondrial disorders, the phenotype may vary depending on the patient's age or the specific gene or genetic variant. Particularly common mitochondrial disease clinical syndromes that present in children include Leigh syndrome (for which there are more than 90 causal genes), mtDNA depletion syndrome (MDS, for which there are dozens of causal genes), mtDNA deletion syndromes (Pearson, Kearns Sayre), primary lactic acidosis, and pyruvate dehydrogenase deficiency. Common clinical features in children present in at least 90 percent of patients include fatigue, exercise intolerance, weakness, gastrointestinal problems, ataxia, and developmental delay. Thus, mitochondrial diseases present to and must be considered by clinicians across every medical specialty.

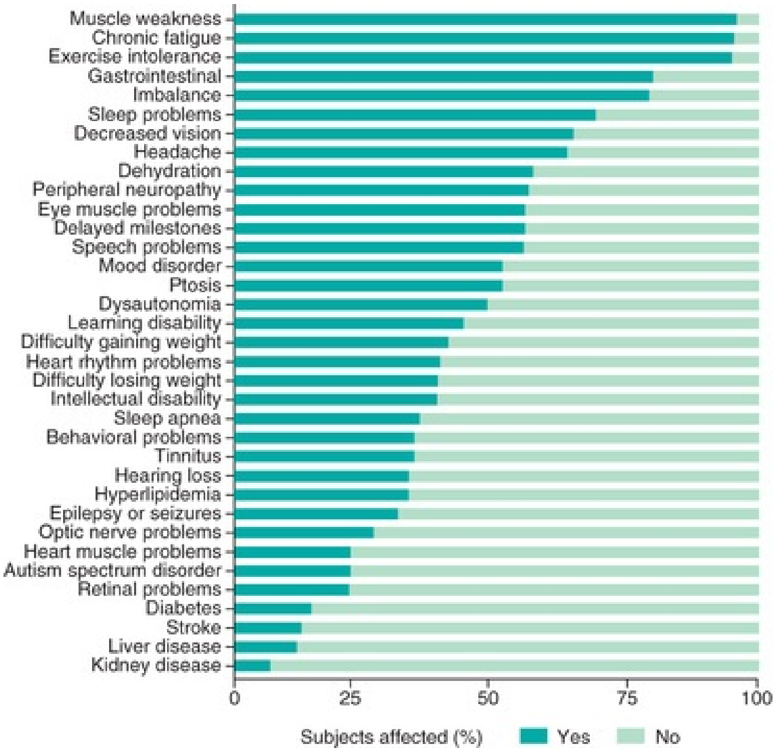

FIG. 106.2 Mitochondrial disease subject cohort, experienced symptoms. Frequency of experienced symptoms as reported by the RDCRN self-reported cohort revealed muscle weakness, chronic fatigue, exercise

intolerance, imbalance, and gastrointestinal problems to be the top 5 common symptoms. (Modified from Zolkipli-Cunningham Z, Xiao R, Stoddart A, et al: Mitochondrial disease patient motivations and barriers to participate in clinical trials. PLoS ONE 13(5):e0197513 [Fig. 2].)

Patients with suspected mitochondrial disease may frequently experience a *diagnostic odyssey* , both clinically and genetically. Their extensive phenotypic heterogeneity without a common biomarker (GDF-15 may be one screening test that may be elevated in some mitochondrial myopathies particularly involving mtDNA deletions or depletion, along with lactic acidosis) presents a challenge to the readily available and accurate **clinical diagnosis** of mitochondrial disorders in many medical settings. Similarly, their extensive genetic heterogeneity involving known etiologies in >300 nuclear genes and all 37 mitochondrial DNA (mtDNA) genes, with likely dozens to hundreds more causative nuclear disease genes awaiting discovery, can make the accurate **genetic diagnosis** of an individual patient challenging. The diagnostic uncertainty can be further compounded by poor genotype-phenotype correlations and variable clinical presentations of individual gene disorders, high locus heterogeneity (i.e., multiple different causal disease genes) for similar clinical phenotypes, incomplete penetrance for some gene disorders, variable life stressors or environmental exposures that may exacerbate a given child's disease, and the unique biologic aspects of maternal inheritance for the subset of mitochondrial diseases caused by mtDNA gene mutations.

When to Suspect Mitochondrial Disease

Because of failure in the ability to generate cellular energy, mitochondrial diseases can involve any organ system at any age (see Fig. 106.2). Mitochondrial disease should be suspected when classic symptoms are present or if unexplained symptoms occur in 3 or more apparently unrelated organs. Individuals may present with a vast array of symptoms, including fatigue, muscle weakness, exercise intolerance, metabolic strokes, seizures, cardiomyopathy, arrhythmias, developmental or cognitive disabilities, autism, diabetes mellitus, other endocrinopathies (adrenal, thyroid), dysautonomia, and autoimmune disorders, as well as impairment of hearing, vision, growth, liver, gastrointestinal (GI), or kidney function. Although individuals may have just one or a few symptoms and a fluctuating disease course in terms of symptom severity, most patients with primary mitochondrial disease tend to develop *progressive* symptoms over time. A study of patients with mitochondrial diseases showed an average of 16 different clinically significant symptoms per patient, with a range of 7-35. When considering the diagnosis, it is helpful to recognize that most symptoms of mitochondrial disease involve *functional,* rather than structural, problems.

When mitochondrial disease is considered in the differential diagnosis, it is often helpful to obtain several **laboratory screening** studies for common biochemical features of mitochondrial disease and overlapping disorders, both at baseline and if unrevealing, during an acute illness or period of decompensation. Blood-based metabolic screening studies include comprehensive chemistry panel, complete blood count with differential, plasma amino acid quantitative analysis, carnitine analysis (total, free, acyl-carnitine profile), ammonia, creatine kinase, and testing for common secondary manifestations of mitochondrial disease (e.g., thyroid screen, lipoprotein profile, hemoglobin A_{1c}). Urine-based metabolic screening studies include urinalysis, urine organic acid quantitative analysis, and urine amino acid quantitative analysis. Consideration should also be given for screening for congenital disorders of glycosylation or vitamin deficiencies, which may have overlapping clinical features in some cases with mitochondrial disease. Lactic acidemia is neither highly sensitive nor specific for primary mitochondrial disease, but laboratory findings suggestive of primary mitochondrial disease include elevations of blood lactate, pyruvate, lactate:pyruvate ratio, alanine, ratios of alanine to lysine (>3) and alanine to sum of phenylalanine and tyrosine (>4), and anion gap. Biochemical alterations further suggestive of mitochondrial disease may include secondary impairment of fatty acid oxidation with elevation of dicarboxylic acids on acyl-carnitine profile, increased branched-chain amino acids and proline on plasma amino acid analysis, increased tricarboxylic acid cycle intermediates and lactate excretion on urine organic acid analysis, and generalized aminoaciduria on urine amino acid analysis. Growth and differentiation factor 15 (**GDF-15**) may be a useful screening test for mitochondrial depletion based myopathies.

Similarly, when mitochondrial disease is considered in the differential diagnosis, obtaining additional **clinical evaluations** to carefully phenotype the patient for prevalent or highly morbid and potentially modifiable features of mitochondrial disease is important. Because many individuals with mitochondrial disease develop problems with their *vision* (reduced visual acuity not correctable with glasses, photophobia or nyctalopia with reduced peripheral vision associated with retinal disease or optic atrophy, ophthalmoplegia, ptosis), *hearing* (high-frequency sensorineural hearing loss), and *heart* (arrhythmia, conduction block, cardiomyopathy), carefully evaluating for involvement of these high-energy systems is indicated. **Neurologic** evaluation is essential because many mitochondrial disease patients experience a range of *central* (metabolic stroke in cortical or deep gray matter including basal ganglia, midbrain, and/or brainstem, white matter changes, seizures, ataxia, movement disorder, migraine, cognitive changes), *peripheral* (axonal sensorimotor neuropathy), or *autonomic* nervous system dysfunction; brain imaging (MRI), spectroscopy (MRS), and on occasion electromyogram or nerve conduction velocity (EMG/NCV) studies can be helpful to support the diagnosis. Formal **exercise physiology** evaluation can also be useful to quantify and advise patients on their exercise capacity and safety, with some specific features (e.g., reduced $V\text{O}_2$ maximal capacity) suggestive of quantifiable mitochondrial dysfunction. **Sleep** study may be useful for individuals with sleep dysfunction because sleep disorders may mimic mitochondrial disease symptoms, and sleep problems are common and potentially treatable in mitochondrial disease. **Gastrointestinal** symptoms are common and underrecognized in mitochondrial disease patients, usually involving dysmotility of any portion of the GI tract with reflux, swallowing dysfunction, delayed gastric emptying, feeding and/or growth problems, pseudoobstruction, malabsorption, and constipation. **Endocrine** abnormalities are also common but underappreciated in many patients, including pituitary, adrenal, thyroid, and pancreatic dysfunction. Such careful phenotyping of patients with suspected mitochondrial disease can thus provide reassurance that the common, and potentially treatable, clinical aspects of mitochondrial disease are not present although they may develop over time, or conversely if identified, increase diagnostic suspicion and direct further diagnostic evaluation.

Mitochondrial Disease Inheritance

Primary mitochondrial disease may result from variants in either nuclear genes or mtDNA genes, which may be inherited from a parent or occur de novo in an affected individual. Thus, all *mendelian* (autosomal recessive, autosomal dominant, X-linked) or *maternal* (mtDNA) inheritance patterns can be consistent with mitochondrial diseases (Table 106.1). Obtaining a detailed, three-generation pedigree is important to potentially highlight the specific inheritance pattern in a given family. Individuals with inherited mtDNA disorders may report family members related through their maternal lineage (both males and females may be affected, but only affected individuals will be connected through the female germline), with a range of functional problems in different organs, such as migraines, fatigue, exercise intolerance, stroke, diabetes mellitus, thyroid dysfunction, irritable bowel spectrum, mood disorder, or vision and hearing problems. Inherited X-linked disorders typically present with symptoms only, or more severely, in males related through unaffected or minimally affected females. **Autosomal recessive** disorders are common in pediatric mitochondrial disease, particularly in consanguineous pedigrees, where a rare variant in the general population becomes enriched and passed down through both maternal and paternal lineages to become homozygous in the affected proband and also affect multiple individuals in a given generation without having affected individuals in earlier generations. **Autosomal dominant** variants may occur de novo or are passed on from either parent to their child, although many disorders may have reduced penetrance, which may make the genetic disorder appear to skip a generation. Identifying a likely inheritance pattern through pedigree analysis can inform accurate interpretation of large-scale genetic diagnostic evaluations, such as multigene sequencing and deletion/duplication analysis panels and exome or genome sequencing. Establishing a correct genetic diagnosis for mitochondrial disease in an affected individual is essential to enable reliable recurrence risk counseling and testing options in a given family, whether in a future pregnancy by chorionic villus sampling (CVS, typically performed at 10-12 weeks' gestation) or amniocentesis (typically performed at 16-20 weeks' gestation) or in the in vitro fertilization (IVF) setting with preimplantation genetic diagnosis (PGD) for a specific disease-causing variant.

Table 106.1

Major Molecular Categories of Mitochondrial Genes

COMPONENT	CAUSAL GENOME	GENE MUTATION EFFECTS	DISEASE EXAMPLES
Electron transport chain enzyme subunits	Nuclear or mtDNA	Decreased functioning of electron transport chain complex	Complex I deficiency Complex II deficiency
Electron transport chain assembly factors	Nuclear	Decreased assembly of electron transport chain enzyme complex	Complex III deficiency Complex IV deficiency Complex V

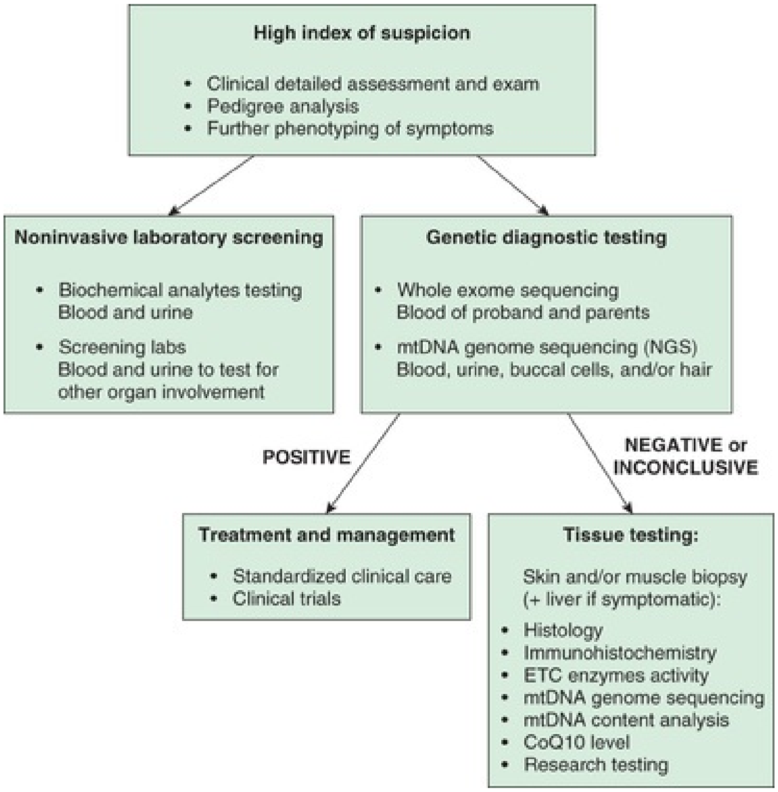
			deficiency
Electron transport chain cofactors	Nuclear	Decreased functioning of electron transport chain	Coenzyme Q10 deficiency Iron sulfur cluster defect Lipoyltransferase deficiency
mtDNA translation	Nuclear or mtDNA	Decreased translation of protein-coding mitochondrial DNA genes leading to decreased functioning of electron transport chain enzymes	Combined oxidative phosphorylation complexes deficiency
mtDNA maintenance	Nuclear	Increased errors in mitochondrial DNA leading to increased presence of point mutations and deletions, resulting in decreased translation of electron transport chain subunits	Mitochondrial DNA depletion syndromes Mitochondrial DNA multiple deletion disorders
Mitochondrial membrane fission and fusion	Nuclear	Increased mtDNA point mutations and deletions; clumped and fragmented mitochondria	*OPA1* -related conditions *MFN2* -related conditions

From McCormick EM, Muraresku CC, Falk MJ: Mitochondrial genomics: a complex field now coming of age. *Curr Genet Med Rep* 6:52–61, 2018 (Table 1, p. 57).

Special mention is warranted to consider the unique aspects of *maternal inheritance* that typify mtDNA disorders. More than 300 disease-causing mtDNA variants have been identified, with extensive variation in disease manifestations and features. Most disease-causing variants are present in only a portion of an individual's mtDNA genomes, a concept known as **heteroplasmy** . For heteroplasmic mtDNA variants, the precise mutation level (percent) can vary between an individual's different tissues and can change over time, with symptom severity corresponding to different threshold mutation levels that can be difficult to define and that typically vary between organs. An individual's mtDNA genome background set of fixed sequence variants, known as a **haplogroup** , can also influence the penetrance or severity of a mtDNA disease. When a novel or rare mtDNA variant is identified in a given individual, it may be useful to use highly sensitive sequencing methods to test the levels of that mutation (which may be accurate to detect 1% mutation levels) in their different tissues (blood, urine, buccal, skin cells, muscle), as well as tissues from their mother or maternal relatives, to accurately determine whether it may be causal of disease in that family. Research-based functional testing may also be necessary to characterize fully the effects of a newly recognized mtDNA variant. When it is not known whether an mtDNA variant is maternally inherited or occurs de novo, the recurrence risk to future offspring of their asymptomatic parent is empirically estimated at 1 in 25 (4%), although the empirical recurrence risk rises to 1 in 2 (50%) when the mother is symptomatic.

Diagnostic Testing for Mitochondrial Disease

The diagnosis of mitochondrial disease relies foremost on genetic testing (genomic analysis), with biochemical screens useful in blood or urine and invasive tissue testing often seen as secondary, or sometimes not required at all (Fig. 106.3).



High index of suspicion
Clinical detailed assessment and exam
Pedigree analysis
Further phenotyping of symptoms
Noninvasive laboratory screening
Biochemical analytes testing Blood and urine
Screening labs Blood and urine to test for other organ involvement
Genetic diagnostic testing
Whole exome sequencing Blood of proband and parents
mtDNA genome sequencing (NGS) Blood, urine, buccal cells, and/or hair
POSITIVE
NEGATIVE or INCONCLUSIVE
Treatment and management
Standardized clinical care
Clinical trials
Tissue testing:
Skin and/or muscle biopsy (+ liver if symptomatic):
Histology
Immunohistochemistry
ETC enzymes activity
mtDNA genome sequencing
mtDNA content analysis
CoQ10 level
Research testing

FIG. 106.3 Diagnostic algorithm for suspected mitochondrial disease. (From Muraresku CC, McCormick EM, Flak MJ: Mitochondrial disease: advances in clinical diagnosis, management, therapeutic development, and preventative strategies. *Curr Genet Med Rep* 6:62–72, 2018.)

When the clinical evaluation—medical history; detailed review of systems; careful physical, neurologic, and dysmorphic examinations; pedigree-, blood-, and urine-based biochemical screening studies; and additional phenotyping clinical evaluations—is suggestive of mitochondrial disease, a range of clinical diagnostic testing options can be pursued. Absent a known molecular etiology in an affected family member, first-line genetic diagnostic testing may involve a focused panel of hundreds to thousands of known nuclear genes and the mtDNA genome using **next-generation sequencing** (NGS) methodologies that will detect both single-nucleotide variants and larger-scale gene deletions and duplications. If such testing is unrevealing, clinically based **whole exome sequencing** (WES) may be pursued. The standard of care is moving to pursue initial diagnostic testing by WES, which is more comprehensive for genes known not only to cause mitochondrial disease, but also to cause all human genetic diseases. The rationale for this evolution in diagnostic testing approach includes the following factors:

1. An increasingly similar cost and turnaround-time for panel-based and WES-based massively parallel NGS studies.
2. The common genetic diagnostic laboratory practice of generating WES data for all tests ordered, but only evaluating and reporting variants in specific gene subsets when panel-based testing is requested, leaving the remaining genes uninterpreted.
3. The mtDNA genome sequence is often included at no extra cost when clinical WES is ordered in blood, but may need to be repeated in a symptomatic tissue (e.g., muscle, liver) to detect heteroplasmic mtDNA variants that may not be present in blood.
4. The utility of performing concurrent proband and both parental sample sequencing *(trio-based testing),* as usually pursued with WES but not panel-based testing, thereby allowing concurrent segregation analysis of a suspected pathogenic variants as well as ready identification of de novo dominant variants in the proband.
5. The improved diagnostic yield of exome relative to panel-based testing increasingly being reported by clinical diagnostic laboratories, given the highly heterogeneous nature of mitochondrial disease, rapid rate of change in the recognition of *new* gene diagnoses making prior established gene panels obsolete, and the extensive phenotypic overlap with non-mitochondrial diseases.
6. The ability to utilize WES raw data (either on a research basis or for reanalysis at a later date by the clinical diagnostic laboratory) to highlight and/or identify “novel” gene disorders not previously

recognized or associated with human disease.

A mitochondrial disease community resource to centrally curate all mitochondrial disease, gene, and variant knowledge across both genomes is publicly accessible at www.mseqdr.org . Exome sequencing including mtDNA is estimated to identify the definitive genetic etiology for mitochondrial disease in at least 60% of patients in whom it is strongly suspected, reducing the diagnostic odyssey in many patients from decades or years to months.

Tissue-based diagnostic testing has decreased in frequency as a front-line test in all patients with suspected mitochondrial disease, although it still has clinical utility in some cases. These include (1) in the setting of rapidly deteriorating clinical status when genetic testing results may not be available in a timely fashion; (2) when a variant of uncertain significance identified on genomic testing has unclear biochemical consequences; and (3) when uninformative genomic sequencing in blood in an individual with myopathy or muscle symptoms raises concern for other disease processes that may be evident on histology, electron microscopy, immunohistochemistry or enzymatic tissue testing. In addition, some mitochondrial diseases are only evident by tissue-based diagnostic testing. These include mtDNA deletion disorders (typically involving several-thousand nucleotides) not present in blood that cause chronic **progressive external ophthalmoplegia** (CPEO) or **Kearns-Sayre syndrome** (KSS) spectrum disorder, as well as different tissue (muscle or liver)-specific mtDNA depletion disorders (e.g., reduced mtDNA tissue content) that confirm a mitochondrial pathophysiology in a given patient and highlight a likely underlying nuclear gene cause for their disease, since mtDNA maintenance requires a host of nuclear-encoded proteins. Muscle analysis for integrated RC oxidative phosphorylation capacity assessment requires analysis of a fresh muscle biopsy only available at a very limited number of sites worldwide, whereas **electron transport chain enzyme** activity analyses are the accepted gold standard to evaluate for mitochondrial dysfunction in a previously frozen tissue sample, often shipped elsewhere for diagnostic analysis. Skin biopsies are useful to establish fibroblast cell lines in which these same studies of mitochondrial function can be clinically performed. If detected, abnormalities can be revealing of a specific type of mitochondrial disorder, although not all mitochondrial diseases may be expressed or detectable in skin analysis. Thus, if fibroblast testing is unrevealing, more invasive tissue studies may subsequently need to be pursued. Fibroblast cell lines, and occasionally blood-based lymphoblastoid cell lines, also provide a minimally invasive cell source to allow other clinical enzymatic analyses to be performed, as well as novel disease gene validation and research-based therapeutic modeling.

Treatment Principles for Mitochondrial Disease

Effective therapies for both primary and secondary mitochondrial diseases are lacking, because little has been known about the biochemical and physiologic abnormalities that contribute to their diverse clinical manifestations. Clinical complexity and imprecisely defined or understood biochemical phenotypes of different mitochondrial disease subtypes have made it difficult for clinicians to effectively apply or monitor targeted therapies for RC disease. *Mitochondrial cocktails* of vitamins and supplements variably include vitamins (B_1 , B_2 , C), antioxidants (CoQ_{10} , lipoic acid, vitamin E), and metabolic modifiers (creatine, L -carnitine, L -arginine, folinic acid). Although the efficacy, toxicity, and optimal dose of these drugs are not known and have not been objectively assessed in human RC disease patients, they continue to be empirically prescribed in hopes of enhancing residual RC enzymatic function or quenching toxic metabolites theorized to accumulate in RC dysfunction, and because of patient-based reports of improved well-being. However, provision of these therapies has often adopted a one-size-fits-all approach, ignoring the inherent variation in primary mitochondrial disease subtypes, the tissue-specific manifestations, and the major pathogenic factors, such as the predominant downstream metabolic and signaling alterations that occur in different disease subclasses.

Although no cure or U.S. Food and Drug Administration (FDA)–approved therapy yet exists for any mitochondrial disease, improved molecular delineation has enabled selected therapies to advance from the theoretical, empirical, and largely ineffective stage to a promising horizon of rational, personalized, and effective interventions. An increasing number of mitochondrial disease diagnoses have interventions involving the initiation or avoidance of specific medications (corticosteroids, valproic acid, phenytoin, barbiturates, propofol for prolonged duration beyond 30-60 min, certain anesthetics, statins, β-blocking agents, amiodarone, nucleoside reverse transcriptase inhibitors), provision of cofactors or diets, and screening regimens for progressive clinical involvement of modifiable manifestations. General therapies for **Leigh syndrome** such as L -arginine and citrulline may prevent or reverse neurodevelopmental sequelae from a metabolic stroke. Nutritional therapies in these disorders are tailored to specific disease genes, such as thiamine and biotin for *SLC19A3* disease, ubiquinol for *PDSS2* (CoQ_{10} deficiency) disease, and thiamine and the ketogenic diet for *PDHA1* (pyruvate dehydrogenase) deficiency. Establishing the precise molecular diagnosis can further be lifesaving by avoiding fasting and mitochondrial-toxic medicines or general anesthetics in specific mitochondrial disease subsets, improving recurrence risk counseling and prevention, enabling targeted screening for reported medical complications, and in some cases providing necessary cofactors or vitamins that may not otherwise have been considered. In addition, reproductive methodologies emerging in some countries for mitochondrial disease prevention, such as **mitochondrial replacement technologies** (MRTs), are only appropriate to consider in the setting of known pathogenic, inherited mtDNA variants. Finally, the ability to molecularly identify primary mitochondrial disease patients has enabled the design of an increasing number of clinical treatment trials now being planned or underway for a diverse range of symptoms that occur in primary mitochondrial diseases (see www.clinicaltrials.gov).

CHAPTER 107

Mucopolysaccharidoses

Jürgen W. Spranger

Mucopolysaccharidoses are hereditary, progressive diseases caused by mutations of genes coding for lysosomal enzymes needed to degrade glycosaminoglycans (acid mucopolysaccharides). *Glycosaminoglycans* (GAGs) are long-chain complex carbohydrates composed of uronic acids, amino sugars, and neutral sugars. The major GAGs are chondroitin-4-sulfate, chondroitin-6-sulfate, heparan sulfate, dermatan sulfate, keratan sulfate, and hyaluronan. These substances are synthesized and, with the exception of hyaluronan, linked to proteins to form *proteoglycans,* major constituents of the ground substance of connective tissue and of nuclear and cell membranes. Degradation of proteoglycans starts with the proteolytic removal of the protein core, followed by the stepwise degradation of the GAG moiety. Failure of this degradation because of absent or grossly reduced activity of mutated lysosomal enzymes results in the intralysosomal accumulation of GAG fragments (Fig. 107.1). Distended lysosomes accumulate in the cell, interfere with cell function, and lead to characteristic patterns of clinical, radiologic, and biochemical abnormalities (Table 107.1 and Fig. 107.2). Within these patterns, specific diseases can be recognized that evolve from the intracellular accumulation of different degradation products (Table 107.2). As a general rule, the impaired degradation of heparan sulfate is more closely associated with **mental deficiency** , and that of dermatan, chondroitin, and keratan sulfate with **mesenchymal abnormalities** . Variable expression within a given entity results from allelic mutations and varying residual activity of mutated enzymes. For instance, allelic mutations of the gene encoding L -iduronidase may result in severe **Hurler disease** (Hurler syndrome) with early death or in mild **Scheie disease** (Scheie syndrome) manifesting only with limited joint mobility, mild skeletal abnormalities, and corneal opacities.

				characteristic bone dysplasia; final height <125 cm		
IVB	Morquio B	AR	*GLB1* 3p21.33	Same as IVA, but milder; adult height >120 cm	β-Galactosidase	L, F, Ac, C
VI	Maroteaux-Lamy	AR	*ARSB* 5q11-q13	Hurler phenotype with marked corneal clouding but normal intelligence; mild, moderate, and severe expression in different families	*N* -Acetylgalactosamine-α-4-sulfate sulfatase (arylsulfatase B)	L, F, Ac
VII	Sly	AR	*GUSB* 7q21.11	Varying from fetal hydrops to mild dysmorphism; dense inclusions in granulocytes	β-Glucuronidase	S, F, Ac, C
IX	Hyaluronidase deficiency	AR	*HYAL1* 3p21.3	Periarticular masses, no Hurler phenotype	Hyaluronidase 1	S
MPSPS	MPS plus syndrome	AR	*VPS33A*	Mild Hurler phenotype, cognitive deficiency, organomegaly, skeletal dysplasia, pancytopenia, renal insufficiency, optic atrophy, early death	No lysosomal enzyme deficiency	

AR, Autosomal recessive; XLR, X-linked recessive; L, Leukocytes; S, serum; F, cultured fibroblasts; Ac, cultured amniotic cells; Af, amniotic fluid; Cv, chorionic villus sampling; MIM, Mendelian Inheritance in Man Catalogue.

Mucopolysaccharidoses are autosomal recessive disorders, with the exception of **Hunter disease** (Hunter syndrome), which is X-linked recessive. Their birth prevalence varies between 1.2 per 100,000 births (United States) and 16.9 per 100,000 births (Saudi Arabia). In the United States the most common subtype is MPS-III, followed by MPS-I and MPS-II.

Disease Entities

Mucopolysaccharidosis I

Mucopolysaccharidosis I (MPS-I) is caused by mutations of the *IUA* gene on chromosome 4p16.3 encoding α-L -iduronidase. Mutation analysis has revealed 2 major alleles, W402X and Q70X, which account for more than half the MPS-I alleles in the white population. The mutations that introduce stop codons with ensuing absence of functional enzyme (null alleles), and in homozygosity or compound heterozygosity, give rise to Hurler syndrome. Other mutations occur in only one or a few individuals.

Deficiency of α-L -iduronidase results in a wide range of clinical involvement, from severe Hurler syndrome to mild Scheie syndrome, which are ends of a broad clinical spectrum. Homozygous nonsense mutations result in severe forms of MPS-I, whereas missense mutations are more likely to preserve some residual enzyme activity associated with a milder form of the syndrome.

Hurler Syndrome

The Hurler form of MPS-I (**MPS I-H**) is a severe, progressive disorder with involvement of multiple organs and tissues that results in premature death, usually by 10 yr of age. An infant with Hurler syndrome appears normal at birth, but inguinal hernias and failed neonatal hearing tests may be early signs. Diagnosis is usually made at 6-24 mo, with evidence of hepatosplenomegaly, coarse facial features, corneal clouding, large tongue, enlarged head circumference, joint stiffness, short stature, and skeletal dysplasia. Acute cardiomyopathy has been found in some infants <1 yr. Most patients have recurrent upper respiratory tract and ear infections, noisy breathing, and persistent copious nasal discharge. Valvular heart disease, notably with incompetence of the mitral and aortic valves, regularly develops, and narrowing of the coronary arteries occurs. Obstructive airway disease, especially during sleep, may necessitate tracheotomy. Obstructive airway disease, respiratory infection, and cardiac complications are the common causes of death (Table 107.3).

Table 107.3

Analysis of Symptom Frequency in Patients With MPS-I ≤2 Yr of Age

SYMPTOMS/COMPLICATIONS	PERCENTAGE OF PATIENTS WITH SYMPTOM
Coarse facies	98
Valvular disease	95
Corneal clouding	90
Hepatomegaly	84

Upper airway obstruction → OSA	82
Kyphosis gibbus	75
Joint contractures	72
Hernia	70
Dysostosis multiplex	70
Cognitive impairment	60
Enlarged tongue	60
Splenomegaly	60
Eustachian tube obstruction → otitis media	55
Hip dysplasia	42
Genu valgum	38
Reactive airway disease	37
Scoliosis	35
Carpal tunnel syndrome	25
Pes cavus	18
Glaucoma	10
Heart failure	3
Cor pulmonale	2

OSA, Obstructive sleep apnea.

From Clarke LA, Atherton AM, Burton BK, et al: Mucopolysaccharidosis type I newborn screening: best practices for diagnosis and management, *J Pediatr* 182:363–370, 2017 (Table 1, p 364).

Most children with Hurler syndrome acquire only limited language skills because of intellectual disability, combined conductive and neurosensory hearing loss, and an enlarged tongue. Progressive ventricular enlargement with increased intracranial pressure caused by communicating hydrocephalus also occurs. Corneal clouding, glaucoma, and retinal degeneration are common. Radiographs show a characteristic skeletal dysplasia known as **dysostosis multiplex** (Figs. 107.3 and 107.4). The earliest radiographic signs are thick ribs and ovoid vertebral bodies. Skeletal abnormalities (in addition to those shown in the figures) include enlarged, coarsely trabeculated diaphyses of the long bones with irregular metaphyses and epiphyses. With disease progression, macrocephaly develops with thickened calvarium, premature closure of lambdoid and sagittal sutures, shallow orbits, enlarged J -shaped sella, and abnormal spacing of teeth with dentigerous cysts.

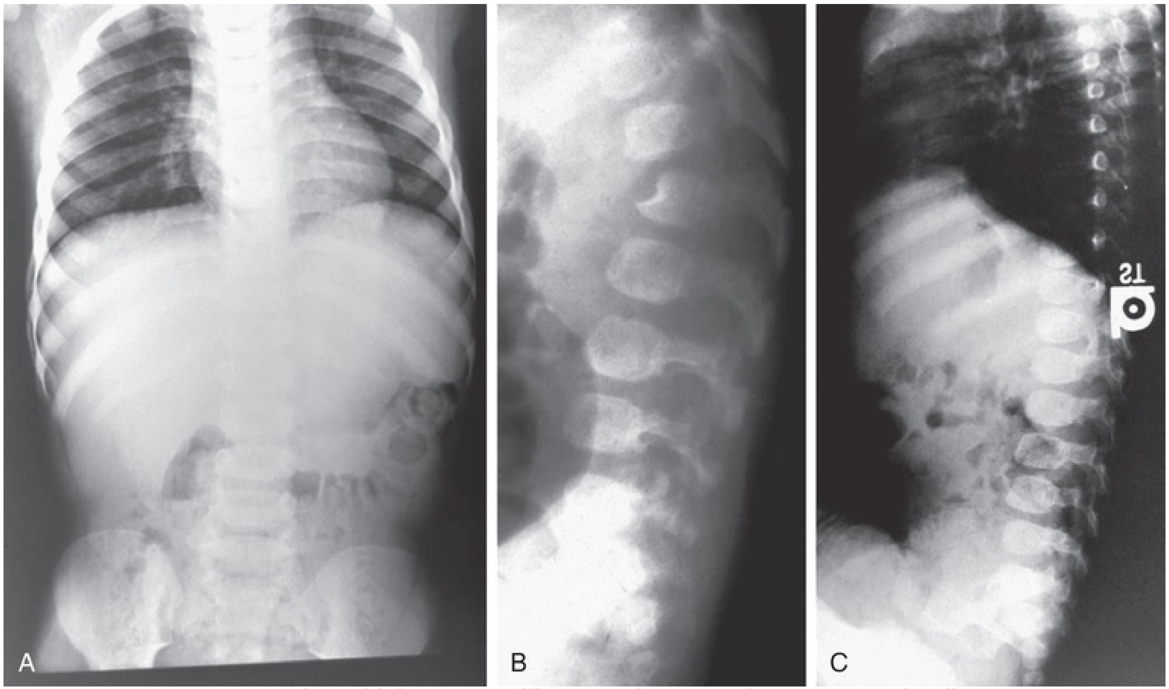

FIG. 107.3 Dysostosis multiplex. A, Sanfilippo syndrome, patient age 4 yr; the ribs are wide. B, Sanfilippo syndrome, age 4 yr; immature, ovoid configuration of the vertebral bodies. C, Hurler syndrome, age 18 mo; anterosuperior hypoplasia of 1st lumbar vertebra (L1) resulting in hook-shaped appearance.

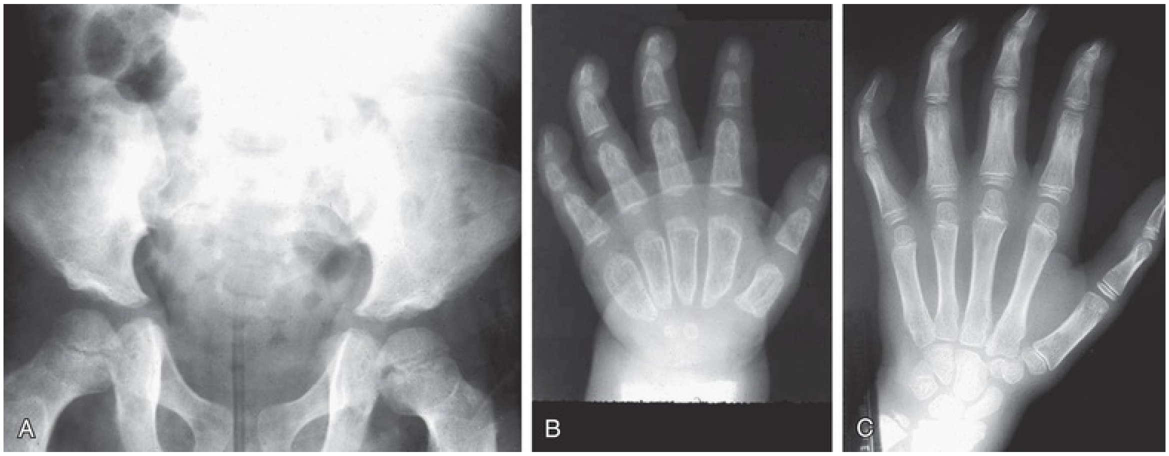

FIG. 107.4 Dysostosis multiplex. A, Mucopolysaccharidosis I-H, patient age 10 yr. The inferior portions of the ilia are hypoplastic, with resulting iliac flare and shallow acetabular fossae. The femoral necks are in valgus position. B, MPS I-H, age 4 yr. Metacarpals and phalanges are abnormally short, wide, and deformed with proximal pointing of the metacarpals and bullet-shaped phalanges. Bone trabeculation is coarse, and the cortices are thin. C, MPS I-S, age 13 yr. The carpal bones are small, leading to a V -shaped configuration of the digits. The short, tubular bones are well modeled. Flexion of the middle and distal phalanges II-V is caused by joint contractures.

Hurler-Scheie Syndrome

The clinical phenotype of the Hurler-Scheie form of MPS-I (**MPS I-H/S**) is *intermediate* between Hurler and Scheie syndromes and is characterized by progressive somatic involvement, including dysostosis multiplex with little or no intellectual dysfunction. The onset of symptoms is usually observed between 3 and 8 yr of age. Survival to adulthood is common. Cardiac involvement and upper airway obstruction contribute to clinical morbidity. Some patients have spondylolisthesis, which may cause cord compression.

Scheie Syndrome

The Scheie form of MPS-I (**MPS I-S**) is a comparatively mild disorder characterized by joint stiffness, aortic valve disease, corneal clouding, and mild dysostosis multiplex. Onset of significant symptoms is usually after age 5 yr, with diagnosis made between 10 and 20 yr. Patients with Scheie syndrome have normal intelligence and stature but have significant joint and ocular involvement. A carpal tunnel syndrome often develops. Ophthalmic features include corneal clouding, glaucoma, and retinal degeneration. Obstructive airway disease, causing sleep apnea, develops in some patients, necessitating tracheotomy. Aortic valve disease is common and has required valve replacement in some patients.

Mucopolysaccharidosis II

Hunter syndrome (MPS-II) is an X-linked disorder caused by the deficiency of iduronate 2-sulfatase. The *IDS* gene is mapped to Xq28. Point mutations of *IDS* have been detected in about 80% of patients with MPS-II. Major deletions or rearrangements of *IDS* have been found in the rest, and these are usually associated with a more severe clinical phenotype. As an X-linked recessive disorder, Hunter syndrome manifests almost exclusively in males. However, it has been observed in females, because of skewed inactivation of the X-chromosome carrying the normal gene.

Marked molecular heterogeneity explains the wide clinical spectrum of Hunter syndrome. Patients with severe MPS-II have features similar to those of Hurler syndrome, except for the lack of corneal clouding and the somewhat slower progression of somatic and central nervous system (CNS) deterioration. Coarse facial features, short stature, dysostosis multiplex, joint stiffness, and intellectual disability manifest between 2 and 4 yr of age. Grouped skin papules are present in some patients. Extensive mongolian spots have been observed in African and Asian patients and may be an early marker of the disease. Gastrointestinal (GI) storage may produce chronic diarrhea. Communicating hydrocephalus and spastic paraplegia may result from thickened meninges. In severely affected patients, extensive, slowly progressive neurologic involvement precedes death, which usually occurs at age 10-15 yr.

Patients with the mild form have a near-normal or normal life span, minimal CNS involvement, and slow progression of somatic deterioration with preservation of cognitive function in adult life. Survival to ages 65 and 87 yr has been reported, and some patients have had children. Somatic features are Hurler-like but milder with a greatly reduced rate of progression. Adult height may exceed 150 cm (60 inches). Airway involvement, valvular cardiac disease, hearing impairment, carpal tunnel syndrome, and joint stiffness are common and can result in significant loss of function in both the mild and severe forms.

Mucopolysaccharidosis III

Sanfilippo syndrome (MPS-III) is a genetically heterogeneous but clinically similar group of 4 recognized types (IIIA-IIID). Each type is caused by a different enzyme deficiency involved in the degradation of heparan sulfate (see Fig. 107.1). Genes encoding these enzymes are listed in Table 107.2 .

Sanfilippo syndrome is characterized by slowly progressive, severe CNS degeneration with mild somatic disease. Onset of clinical features usually occurs at age 2–6 yr in a child who previously appeared normal. Presenting features include delayed cognitive development, hyperactivity with aggressive behavior, coarse hair, hirsutism, sleep disorders, and mild hepatosplenomegaly. Delay in diagnosis of MPS-III is common because of the mild physical features, hyperactivity, and slowly progressive neurologic disease. Severe neurologic deterioration occurs in most patients by age 6-10 yr, accompanied by rapid deterioration of social and adaptive skills. Severe behavior problems are common, such as sleep disturbance, uncontrolled hyperactivity, temper tantrums, destructive behavior, and physical aggression. Profound intellectual disability and behavior problems often occur in patients with normal physical strength, making management particularly difficult.

Mucopolysaccharidosis IV

Morquio syndrome (MPS-IV) is caused by a deficiency of *N* -acetylgalactosamine-6-sulfatase (**MPS-IVA**) or of β-galactosidase (**MPS-IVB**). Both result in the defective degradation of keratan sulfate. The gene encoding *N* -acetylgalactosamine-6-sulfatase is *GALNS* on chromosome 16q24.3, and the gene encoding β-galactosidase is *GLB1* on chromosome 3p21.33. β-Galactosidase catalyzes GM_1 ganglioside in addition to endohydrolysis of keratan sulfate, and most mutations of *GLB1* result in generalized **gangliosidosis** , a spectrum of neurodegenerative disorders associated with dysostosis multiplex. A W273L mutation of the *GLB1* gene, either in the homozygous state or as part of compound heterozygosity, usually results in Morquio B syndrome.

Both types of Morquio syndrome are characterized by short-trunk dwarfism, a skeletal dysplasia that is distinct from other mucopolysaccharidoses, and preservation of intelligence. MPS-IVA is usually more severe than MPS-IVB, with adult height of <125 cm (50 inches) and >150 cm, respectively. However, there is considerable variability of expression in both subtypes. The appearance of genu valgum, kyphosis, growth retardation with short trunk and neck, and waddling gait with a tendency to fall are early symptoms of MPS-IV. Extraskeletal manifestations include mild corneal clouding, small teeth with abnormally thin enamel, frequent caries formation, and occasionally hepatomegaly and cardiac valvular lesions. Instability of the odontoid process and ligamentous laxity are invariably present and can result in life-threatening atlantoaxial instability and dislocation. Thickened anterior extradural tissue contributes to spinal cord compression. Regular neurologic assessment and radiologic imaging are imperative. Surgery to stabilize the upper cervical spine, usually by posterior spinal fusion, before the development of cervical myelopathy, can be lifesaving.

Mucopolysaccharidosis VI

Maroteaux-Lamy syndrome (MPS-VI) is caused by mutations of the *ARSB* gene on chromosome 5q11-13 encoding *N* -acetylgalactosamine-4-sulfatase (arylsulfatase B). It is characterized by severe to mild somatic involvement, as seen in MPS-I, but with preservation of intelligence. The somatic involvement of the severe form of MPS-IV is characterized by corneal clouding, coarse facial features, joint stiffness, valvular heart disease, communicating hydrocephalus, and dysostosis multiplex. In the severe form, growth can be normal for the 1st few years of life but seems to virtually stop after age 6-8 yr. The mild to intermediate forms of Maroteaux-Lamy syndrome can be easily confused with Scheie syndrome. Spinal cord compression from thickening of the dura in the upper cervical canal with resultant myelopathy is common in patients with MPS-VI.

Mucopolysaccharidosis VII

Sly syndrome (MPS-VII) is caused by mutations of the *GUSB* gene located on chromosome 7q21.11. Mutations result in a deficiency of ß-glucuronidase, intracellular storage of GAG fragments, and extensive clinical involvement. The most severe form presents as lethal **nonimmune fetal hydrops** and may be detected in utero by ultrasound. Some severely affected newborns survive for months and have, or develop, signs of lysosomal storage disease, including thick skin, visceromegaly, and dysostosis multiplex. Less severe forms of MPS-VII present during the 1st years of life with features of MPS-I but slower progression. Corneal clouding varies. Patients with manifestation after 4 yr of life have skeletal abnormalities of dysostosis multiplex but normal intelligence and usually clear corneas. They may be found incidentally on the basis of a blood smear that shows coarse granulocytic inclusions.

Mucopolysaccharidosis IX

MPS-IX is caused by a mutation in the *HYAL1* gene on chromosome 3p21.2-21.2 encoding 1 of 3 hyaluronidases. Clinical findings in the only known patient, a 14 yr old girl, were bilateral nodular soft tissue periarticular masses, lysosomal storage of GAGs in histiocytes, mildly dysmorphic craniofacial features, short stature, normal joint movement, and normal intelligence. Small erosions in both acetabula were the only radiographic findings.

Mucopolysaccharidosis Plus Syndrome

Coarse facial features, organomegaly, joint contractures, dysostosis multiplex, cognitive deficiency, increased mucopolysacchariduria, and massive intracellular accumulation of heparin sulfate were found in 13 children in Northeastern Siberia and 2 Turkish children. Further findings were optic atrophy, intracerebral calcifications, pancytopenia, and renal insufficiency. Most patients died within the 1st 2 yr of life from cardiorespiratory failure.

Lysosomal enzyme activities were normal in children with MPS plus syndrome. This autosomal recessive multisystem disorder is caused by homozygous mutations of *VPS33A* encoding a protein involved in lysosomal fusion processes.

Diagnosis and Differential Diagnosis

Clinical suspicion of a MPS justifies a skeletal survey. Radiographs of chest, spine, pelvis, and hands may show signs of dysostosis multiplex. The next diagnostic step is to assay the urinary excretion of GAGs. Semiquantitative spot tests for increased urinary GAG excretion are quick, inexpensive, and useful for initial evaluation but are subject to both false-positive and false-negative results. Quantitative analysis of single GAG and/or oligosaccharides by mass spectrometry detection tests reveals type-specific profiles in urine, serum, plasma, and dried blood spots.

Any individual with a suspected MPS disorder based on clinical features, radiographic results, or urinary GAG screening tests should have a definitive diagnosis established by **enzyme assay** . Serum, leukocytes, or cultured fibroblasts are used as the tissue source for measuring lysosomal enzymes (see Table 107.2).

Molecular analysis is typically performed using appropriate gene panels. In many cases the type and location of the mutation are related to the future course of the disease and thus have a predictive value. The specific mutation is also needed if **prenatal diagnosis** on fetal cells from a subsequent pregnancy is considered. Carrier testing in Hunter syndrome, an X-linked disorder, requires analysis of *IDS* once the specific mutation or chromosome arrangement in the family is known. Prenatal molecular analysis must be offered in a male fetus of a proven female carrier of the *IDS* gene. His risk to be affected is 50%. In a female fetus the risk is small, but not zero, as a result of skewed maternal X-chromosome inactivation.

Newborn screening for mucopolysaccharidoses is available from dried blood spots and is essential for their early detection and therapeutic intervention.

Mucolipidoses and **oligosaccharidoses** manifest with the same clinical and radiographic features as mucopolysaccharidoses. In these conditions the urinary excretion of GAGs is not elevated. Hurler-like facial features, joint contractures, dysostosis multiplex, and elevated urinary GAG excretion differentiate the mucopolysaccharidoses from other neurodegenerative and dwarfing conditions.

Treatment

Hematopoietic stem cell transplantation has resulted in significant clinical improvement of somatic disease in patients with MPS I, II, and VI (Table 107.4). Clinical effects are increased life expectancy with resolution or improvement of growth, hepatosplenomegaly, joint stiffness, facial appearance, skin changes, obstructive sleep apnea, heart disease, communicating hydrocephalus, and hearing loss. Enzyme activity in serum and urinary GAG excretion normalize. This is true for MPS I-H, II, and III. Patients with MPS-I who have undergone transplantation before 9 mo of age may show normal cognitive development. Transplantation before 24 mo and with a baseline mental development index >70 have improved long-term outcome. Transplantation does not significantly improve the neuropsychological outcome of MPS patients with impaired cognition at transplantation. Early transplantation in the MPS-II patient may have the same effect. Transplantation in the MPS-VI patient stabilizes or improves cardiac manifestations, posture, and joint mobility. Stem cell transplantation does not correct skeletal or ocular anomalies.

Table 107.4

Therapies Aimed at Proximate Causes of Mucopolysaccharidoses

MPS TYPE	HEMATOPOIETIC STEM CELL TRANSPLANTATION	ENZYME REPLACEMENT THERAPY	REMARKS
I	Yes	Laronidase (Aldurazyme)	Developmental trajectory dependent on time of transplantation. Little effect on connective tissue manifestations. Enzyme replacement immediately after diagnosis.
II	Yes	Idursulfase (Elaprase)	
III	No	No	Experimental intrathecal application of recombinant heparin-*N* -sulfatase in MPS-IIIA.
IV	Yes	Elosulfase (Vimizim)	Improved daily activities. No effect on growth or skeletal dysplasia.
VI	Yes	Galsulfase (Naglazyme)	Improved daily activities. Improved growth. No effect on skeletal dysplasia.
VII	Yes	rhGUS	Phase 3 study by Ultragenyx, 2016. Limited experience because of rarity of condition.

Enzyme replacement therapy (ERT) using recombinant α-L -iduronidase has been approved for patients with MPS-I (Table 107.4). It reduces organomegaly and ameliorates rate of growth, improves joint mobility, and reduces the number of episodes of sleep apnea and urinary GAG excretion. The enzyme does not cross the blood-brain barrier and does not prevent deterioration of neurocognitive function. Consequently, ERT is appropriate for patients with mild CNS involvement or to stabilize extraneural manifestations in young patients before stem cell transplantation. Recombinant iduronate-2-sulfatase is the treatment of choice for MPS-II to ameliorate nonneural manifestations. ERT with recombinant human *GALNS* improves physical endurance, respiratory function, and daily living activity of patients with MPS-IV. Similar effects produce recombinant *N* -acetylgalactosamine-4-sulfatase in patients with MPS-VI.

Symptomatic therapy focuses on respiratory and cardiovascular complications, hearing loss, carpal tunnel syndrome, spinal cord compression, hydrocephalus, and other problems (Table 107.5). The multisystem involvement and progressive nature of MPS syndromes usually requires the complex care provided by medical centers.

Table 107.5

Symptomatic Management of Mucopolysaccharidoses

PROBLEM	PREDOMINANTLY IN	MANAGEMENT
NEUROLOGIC		
Hydrocephalus	MPS I, II, VI, VII	Funduscopy, CT scan Ventriculoperitoneal shunting
Chronic headaches	All	
Behavioral disturbance	MPS-III	Behavioral medication, sometimes CT scan, ventriculoperitoneal shunting
Disturbed sleep–wake cycle	MPS-III	Melatonin
Seizures	MPS I, II, III	EEG, anticonvulsants
Atlantoaxial instability	MPS IV	Cervical MRI, upper cervical fusion
Spinal cord compression	All	Laminectomy, dural excision
OPHTHALMOLOGIC		
Corneal opacity	MPS I, VI, VII	Corneal transplant
Glaucoma	MPS I, VI, VII	Medication, surgery
Retinal degeneration	MPS I, II	Night-light
EARS, AIRWAYS		
Recurrent otitis media	MPS I, II, VI, VII	Ventilating tubes
Impaired hearing	All except MPS-IV	Audiometry, hearing aids
Obstruction	All except MPS-III	Adenotomy, tonsillectomy, bronchodilator therapy, CPAP at night,

		laser excision of tracheal lesions, tracheotomy
CARDIAC		
Cardiac valve disease	MPS I, II, VI, VII	Endocarditis prevention, valve replacement
Coronary insufficiency	MPS I, II, VI, VII	Medical therapy
Arrhythmias	MPS I, II, VI, VII	Antiarrhythmic medication, pacemaker
ORAL, GASTROINTESTINAL		
Hypertrophic gums, poor teeth	MPS I, II, VI, VII	Dental care
Chronic diarrhea	MPS-II	Diet modification, loperamide
MUSCULOSKELETAL		
Joint stiffness	All except MPS IV	Physical therapy
Weakness	All	Physical therapy, wheelchair
Gross long-bone malalignment	All	Corrective osteotomies
Carpal tunnel syndrome	MPS I, II, VI, VII	Electromyography, surgical decompression
ANESTHESIA	All except III	Avoid atlantoaxial dislocation; use angulated video intubation laryngoscope and small endotracheal tubes.

CHAPTER 108

Disorders of Purine and Pyrimidine Metabolism

James C. Harris

The inherited disorders of purine and pyrimidine metabolism cover a broad spectrum of illnesses with various presentations. These include hyperuricemia, acute renal failure, renal stones, gout, unexplained neurologic deficits (seizures, muscle weakness, choreoathetoid and dystonic movements), intellectual and developmental disabilities, acrofacial dysostosis, compulsive self-injury and aggression, autistic-like behavior, unexplained anemia, failure to thrive, susceptibility to recurrent infection (immune deficiency), and deafness. When identified, all family members should be screened.

Purines and pyrimidines form the basis of *nucleotides* and *nucleic acids* (DNA and RNA) and thus are involved in all biologic processes. Metabolically active nucleotides are formed from heterocyclic nitrogen-containing purine bases (guanine and adenine) and pyrimidine bases (cytosine, uridine, and thymine): all cells require a balanced supply of nucleotides for growth and survival. Purines provide the primary source of cellular energy through adenosine triphosphate (ATP) and the basic coenzymes (nicotinamide adenine dinucleotide and its reduced form) for metabolic regulation and play a major role in signal transduction (guanosine triphosphate [GTP], cyclic adenosine monophosphate, cyclic guanosine monophosphate). Fig. 108.1 shows the early steps in the biosynthesis of the purine ring. Purines are primarily produced from endogenous sources, and in usual circumstances, dietary purines have a small role. The end product of purine metabolism in humans is uric acid (2,6,8-trioxypurine).

Uric acid is not a specific disease marker, so the cause of its elevation must be determined. The serum level of uric acid present at any time depends on the size of the purine nucleotide pool, which is derived from de novo purine synthesis, catabolism of tissue nucleic acids, and increased turnover of preformed purines. Uric acid is poorly soluble and must be excreted continuously to avoid toxic accumulation in the body. Baseline serum uric acid is established by the balancing of activity between secretory and absorptive urate transporters in both kidney and intestine. Urate secretion and absorption are mediated by separate, opposing groups of transporters. The majority of the genes involved in the variation in uric acid blood level encode urate transporters or associated regulatory proteins.

Thus the fraction of uric acid excreted by the kidney is the result of a complex interplay between secretion and reabsorption by specific and nonspecific uric acid transporters in the proximal tubule, and this sets the level of uric acid in the plasma. Because renal tubule excretion is greater in children than in adults, serum uric acid levels are a less reliable indicator of uric acid production in children than in adults, and therefore measurement of the level in urine may be required to determine excessive production. Clearance of a smaller portion of uric acid is through the gastrointestinal (GI) tract (biliary and intestinal secretion). Because of poor solubility of uric acid under normal circumstances, uric acid is near the maximal tolerable limits, and small alterations in production or solubility or changes in secretion may lead to hyperuricemia and can result in precipitation monosodium urate crystals in extremities (e.g., fingers or toes), which defines **clinical gout** . In renal insufficiency, urate excretion is increased by residual nephrons and the GI tract. Increased production of uric acid is found in malignancy, Reye syndrome, Down syndrome, psoriasis, sickle cell anemia, cyanotic congenital heart disease, pancreatic enzyme replacement, glycogen storage disease (types I, III, IV, and V), hereditary fructose intolerance, and acyl-coenzyme A dehydrogenase deficiency.

The metabolism of both purines and pyrimidines can be divided into biosynthetic, salvage, and catabolic pathways. The first, the de novo pathway, involves a multistep biosynthesis of phosphorylated ring structures from precursors such as CO_2 , glycine, and glutamine. Purine and pyrimidine nucleotides are produced from ribose-5-phosphate or carbamyl phosphate, respectively. The second, a single-step salvage pathway, recovers purine bases and pyrimidine nucleosides derived from either dietary intake or the catabolic pathway (Figs. 108.2 and 108.3). In the de novo pathway, the nucleosides guanosine, adenosine, cytidine, uridine, and thymidine are formed by the addition of ribose-1-phosphate to the purine bases guanine or adenine and to the pyrimidine bases cytosine, uracil, and thymine, respectively. The phosphorylation of these nucleosides produces monophosphate, diphosphate, and triphosphate nucleotides, as well as the deoxy-nucleotides that are utilized for DNA formation. Under usual circumstances, the salvage pathway predominates over the biosynthetic pathway because nucleotide salvage saves energy for cells. Only a small fraction of the nucleotides turned over by the body each day are degraded and excreted. Synthesis of nucleotides is most active in tissues with high rates of cellular turnover, such as gut epithelium, skin, and bone marrow. The third pathway is catabolism. The end product of the catabolic pathway of the purines in humans is uric acid, whereas catabolism of pyrimidines produces citric acid cycle intermediates.

FIG. 108.3 Pathways in pyrimidine biosynthesis.

Inborn errors in the **synthesis of purine nucleotides** comprise the phosphoribosylpyrophosphate synthetase spectrum of disorders, including deficiency and superactivity, adenylosuccinate lyase deficiency, and 5-amino-4-imizolecarboxamide (AICA) riboside deficiency (AICA-ribosiduria). Disorders resulting from abnormalities in **purine catabolism** comprise muscle adenosine monophosphate (AMP) deaminase deficiency, adenosine deaminase deficiency, purine nucleoside phosphorylase deficiency, and xanthine oxidoreductase deficiency. Disorders resulting from the **purine salvage** pathway include hypoxanthine-guanine phosphoribosyltransferase (HPRT) deficiency and adenine phosphoribosyltransferase (APRT) deficiency.

Hereditary orotic aciduria (uridine monophosphate synthase deficiency) is an inborn error of **pyrimidine synthesis** that leads to an excessive excretion of orotic acid in urine. Dihydrorotate dehydrogenase deficiency (Miller syndrome), also a disorder of de novo pyrimidine synthesis, paradoxically may lead to orotic aciduria. Other pyrimidine disorders lead to abnormalities in **pyrimidine catabolism** , including dihydropyrimidine dehydrogenase (DPD) deficiency, dihydropyrimidinase (DPH) deficiency, β-ureidopropionase deficiency, pyrimidine 5′-nucleotidase deficiency, and thymidine phosphorylase deficiency. A disorder resulting from the **pyrimidine salvage** is thymidine kinase-2 deficiency.

Gout

Gout presents with hyperuricemia, uric acid nephrolithiasis, and acute inflammatory arthritis. **Gouty arthritis** is caused by monosodium urate crystal deposits that result in inflammation in joints and surrounding tissues. The presentation is most commonly monoarticular, typically in the metatarsophalangeal joint of the big toe. *Tophi*, deposits of monosodium urate crystals, may occur over points of insertion of tendons at the elbows, knees, and feet or over the helix of the ears. **Primary gout** usually occurs in middle-aged males and results mainly from decreased renal excretion of uric acid, or purine overconsumption, or high intake of alcohol or fructose, or a combination of these factors. Gout occurs in any condition that leads to reduced clearance of uric acid: during therapy for malignancy or with dehydration, lactic acidosis, ketoacidosis, starvation, diuretic therapy, and renal failure. Excessive purine, alcohol, or fructose ingestion may increase uric acid levels. The biochemical etiology of gout is unknown for most patients, and it is considered to have a basis in genetic polymorphisms, predominantly in uric acid transporters. Purine overproduction is a rare cause of primary gout and is associated with several genetic disorders discussed later. **Secondary gout** is either the result of another disorder with rapid tissue breakdown or cellular turnover, leading to increased production or decreased excretion of uric acid, or the result of some types of drug treatment; for example, diuretics cause plasma volume reduction and can precipitate a gouty attack.

Gout resulting from **endogenous purine overproduction** is associated with hereditary disorders of 3 different enzymes that result in hyperuricemia. These include the HPRT deficiency spectrum (ranging from severe deficiency or Lesch-Nyhan syndrome to partial HPRT deficiency), 2 forms of superactivity of PP-ribose-P synthetase, and glycogen storage disease type I (glucose-6-phosphatase deficiency). In the first 2 disorders, the basis of hyperuricemia is purine nucleotide and uric acid overproduction, whereas in the 3rd disorder it is both excessive uric acid production and diminished renal excretion of urate. Glycogen storage disease types III, V, and VII are associated with exercise-induced hyperuricemia, the consequence of rapid ATP utilization and failure to regenerate it effectively during exercise (see Chapter 105.1).

Juvenile gout results from purine underexcretion. The earlier terminology *juvenile hyperuricemic nephropathy* has been replaced by the newer term (autosomal dominant) *tubulointerstitial kidney disease* (ADTKD). The term **ADTKD-UMOD** *(uromodulin-associated kidney disease)* is used for medullary cystic kidney disease type 2 and maps to chromosome 16p11.2. It results from uromodulin mutations. Other genes classified as forms of familial juvenile hyperuricemic nephropathy include those for renin and hepatic nuclear factor-1β. Unlike the 3 inherited purine disorders that are X-linked and the recessively inherited glycogen storage disease, these are autosomal dominant conditions. Familial juvenile hyperuricemic nephropathy is associated with a reduced fractional excretion of uric acid. Although it typically presents from puberty up to the 3rd decade, it has been reported in early childhood. It is characterized by early onset, hyperuricemia, gout, familial renal disease, and low urate clearance relative to glomerular filtration rate. It occurs in both males and females and is frequently associated with a rapid decline in renal function that may lead to death unless diagnosed and treated early. Once familial juvenile hyperuricemic nephropathy is recognized, presymptomatic detection is of critical importance to identify asymptomatic family members with hyperuricemia and to begin treatment, when indicated, to prevent nephropathy.

Genetics

Familial juvenile hyperuricemic nephropathy-2 (HNFJ2; 613092) is caused by mutation in the renin gene (*REN* ; 179820) on chromosome 1q32. HNFJ3 (614227) has been mapped to chromosome 2p22.1-p21. ADTKD involves mutations of the mucin *(MUC1)* gene. The mutation of uromodulin has been traced to chromosome 16.

Treatment

Treatment of hyperuricemia involves the combination of allopurinol or febuxostat (xanthine oxidase inhibitors) to decrease uric acid production, probenecid to increase uric acid clearance in those with normal renal function, and increased fluid intake to reduce the concentration of uric acid. A low-purine diet, weight reduction, and reduced alcohol and fructose intake (fructose both reduces urate clearance and accelerates ATP breakdown to uric acid) are recommended.

Abnormalities in Purine Salvage

Hypoxanthine-Guanine Phosphoribosyltransferase (HPRT) Deficiency

Lesch-Nyhan disease (LND) is a rare X-linked disorder of purine metabolism that results from HPRT deficiency. This enzyme is normally present in each cell in the body, but its highest concentration is in the brain, especially in the basal ganglia. Clinical manifestations include hyperuricemia, intellectual disability, dystonic movement disorder that may be accompanied by choreoathetosis and spasticity, dysarthric speech, and compulsive self-biting, usually beginning with the eruption of teeth.

There is a spectrum of severity for the clinical presentations. HPRT levels are related to the extent of motor symptoms, to the presence or absence of self-injury, and possibly to the level of cognitive function. Purine overproduction is present. The majority of individuals with classic LND have low or undetectable levels of the HPRT enzyme. Partial deficiency in HPRT (**Kelley-Seegmiller syndrome**) with >1.5–2.0% enzyme is associated with purine overproduction and variable neurologic dysfunction (neurologic HPRT deficiency). HPRT deficiency with activity levels >8% of normal still shows purine (and uric acid) overproduction but apparently normal cerebral functioning (HPRT-related hyperuricemia), although cognitive deficits may occur. Qualitatively similar cognitive deficit profiles have been reported in both LND and variant cases. Variants produced scores intermediate between those of patients with LND and normal controls on almost every neuropsychological measure tested.

Genetics

The *HPRT* gene has been localized to the long arm of the X chromosome (q26-q27). The complete amino acid sequence for HPRT is known and is encoded by the *HPRT1* gene (approximately 44 kb; 9 exons). The disorder appears in males; occurrence in females is extremely rare and ascribed to nonrandom inactivation of the normal X chromosome. Absence of HPRT activity results in a failure to salvage hypoxanthine, which is degraded to uric acid. Failure to consume phosphoribosylpyrophosphate in the salvage reaction results in an increase in this metabolite, which drives de novo purine synthesis, leading to the overproduction of uric acid. Excessive uric acid production manifests as gout, necessitating specific drug treatment (allopurinol). Because of the enzyme deficiency, hypoxanthine accumulates in the cerebrospinal fluid (CSF), but uric acid does not; uric acid is not produced in the brain and does not cross the blood-brain barrier. The behavior disorder is not caused by hyperuricemia or excess hypoxanthine because patients with partial HPRT deficiency, the variants with hyperuricemia, do not self-injure, and infants with isolated hyperuricemia from birth do not develop self-injurious behavior.

The prevalence of the classic LND has been estimated at 1 in 100,000 to 1 in 380,000 persons based on the number of known cases in the United States. The incidence of partial variants is not known. Those with the classic syndrome rarely survive the 3rd decade because of renal or respiratory compromise. The life span may be normal for patients with partial HPRT deficiency without severe renal involvement.

Pathology

No specific brain abnormality is documented after detailed histopathology and electron microscopy of affected brain regions. MRI has documented reductions in the volume of basal ganglia nuclei. Abnormalities in neurotransmitter metabolism have been identified in 3 autopsied cases. All 3 patients had very low HPRT levels (<1% in striatal tissue and 1–2% of control in thalamus cortex). There was a functional loss of 65–90% of the nigrostriatal and mesolimbic dopamine terminals, although the cells of origin in the substantia nigra did not show dopamine reduction. The brain regions primarily involved were the caudate nucleus, putamen, and nucleus accumbens. It is proposed that the neurochemical changes may be linked to functional abnormalities, possibly resulting from a diminution of arborization or branching of dendrites rather than cell loss. A neurotransmitter abnormality is demonstrated by changes in CSF neurotransmitters and their metabolites and is confirmed by positron emission tomography (PET) scans of dopamine function. In vivo reductions in the presynaptic dopamine transporter have been documented in the caudate and putamen of 6 individuals.

The mechanism whereby HPRT leads to the neurologic and behavioral symptoms is unknown. However, both hypoxanthine and guanine metabolism are affected, and GTP and adenosine have substantial effects on neural tissues. The functional link between purine nucleotides and the dopamine system is through salvage of guanine by HPRT to form GTP; this is essential for GTP cyclohydrolase activity, the first step in the synthesis of pterins and dopamine. In a controlled study that sought correlations between HPRT and GPRT and behavior, GPRT was more highly correlated than HPRT on 13 of 14 measures of the clinical phenotype; these included severity of dystonia, cognitive impairment, and behavioral abnormalities. These findings suggest that loss of guanine recycling might be more closely linked to the LND/LNV phenotype than loss of hypoxanthine recycling. Moreover, patients with inherited GTP cyclohydrolase deficiency show clinical features in common with LND.

Dopamine reduction in brain is documented in HPRT-deficient strains of mutant mice. Dopamine binding to its receptor results in either an activation (D1 receptor) or an inhibition (D2 receptor) of adenylcyclase. Both receptor effects are mediated by G proteins (GTP-binding proteins) dependent on guanine diphosphate in the guanine diphosphate/GTP exchange for cellular activation. Dopamine and adenosine systems are also linked through the role of adenosine as a neuroprotective agent in preventing neurotoxicity. Adenosine derives from AMP, which depends on hypoxanthine salvage in the brain by HPRT. Adenosine agonists mimic the biochemical and behavioral actions of dopamine antagonists, whereas adenosine receptor antagonists act as functional dopamine agonists. LND can thus be seen as arising ultimately from nucleotide depletion specifically in the brain, which relies on the HPRT salvage pathway, leading to dopamine and adenosine depletions.

Clinical Manifestations

At birth, infants with LND have no apparent neurologic dysfunction. After several months, developmental delay and neurologic signs become apparent. Before age 4 mo, hypotonic, recurrent vomiting, and difficulty with secretions may be noted. By 8-12 mo, extrapyramidal signs appear, primarily dystonic movements. In some patients, spasticity may become apparent at this time; in others it becomes apparent later in life.

Cognitive function is usually reported to be in the mild to moderate range of intellectual disability, although some individuals test in the low-normal range. Because test scores may be influenced by difficulty in testing caused by movement disorder and dysarthric speech, overall intelligence may be underestimated.

The age of onset of self-injury may be as early as 1 yr and occasionally as late as the teens. Self-injury occurs, although all sensory modalities, including pain, are intact. The **self-injurious behavior** (SIB) usually begins with self-biting, although other SIB patterns emerge with time. Most characteristically, the fingers, mouth, and buccal mucosa are mutilated. Self-biting is intense and causes tissue damage and may result in the amputation of fingers and substantial loss of tissue around the lips. Extraction of primary teeth may be required. The biting pattern can be asymmetric, with preferential mutilation of the left or right side of the body. The type of behavior is different from that seen in other intellectual disability syndromes involving self-injury. Self-hitting and head-banging are the most common initial presentations in *other* syndromes. The intensity of SIB generally requires that the patient be restrained. When restraints are removed, the patient with LND may appear terrified, and stereotypically place a finger in the mouth. The patient may ask for restraints to prevent elbow movement; when the restraints are placed, or replaced, he may appear relaxed and cheerful. Dysarthric speech may cause interpersonal communication problems; however, the higher-functioning children can express themselves fully and participate in verbal therapy.

The self-mutilation presents as a compulsive behavior that the child tries to control but frequently is unable to resist. Older individuals may enlist the help of others and notify them when they are comfortable enough to have restraints removed. In some cases the behavior may lead to deliberate self-harm. The LND patient may also show compulsive aggression and inflict injury to others through pinching, grabbing, or hitting or by using verbal forms of aggression. Afterward he may apologize, stating that this behavior was out of his control. Other maladaptive behaviors include head- or limb-banging, eye-poking, and psychogenic vomiting.

Diagnosis

The presence of **dystonia** along with self-mutilation of the mouth and fingers suggests LND. With partial HPRT deficiency, recognition is linked to either hyperuricemia alone or hyperuricemia and a dystonic movement disorder. Serum levels of uric acid that exceed 4-5 mg uric acid/dL and a urine uric acid:creatinine ratio of ≥3-4 : 1 are highly suggestive of HPRT deficiency, particularly when associated with neurologic symptoms. The definitive diagnosis requires an analysis of the HPRT enzyme. This is assayed in an erythrocyte lysate. Individuals with classic LND have near 0% enzyme activity, and those with partial variants show values between 1.5% and 60%. The intact cell HPRT assay in skin fibroblasts offers a good correlation between enzyme activity and severity of disease. Molecular techniques are used for gene sequencing and identification of carriers.

Differential diagnosis includes other causes of infantile hypotonia and dystonia. Children with LND are often initially *incorrectly* diagnosed as having athetoid cerebral palsy. When a diagnosis of cerebral palsy is suspected in an infant with a normal prenatal, perinatal, and postnatal course, LND should be considered. Partial HPRT deficiency may be associated with acute renal failure in infancy; therefore clinical awareness of partial HPRT deficiency is of particular importance. The simplest test to exclude LND or partial deficiency is the urinary uric acid:creatinine ratio.

An understanding of the molecular disorder has led to effective drug treatment for uric acid accumulation and arthritic tophi, renal stones, and neuropathy. However, reduction in uric acid alone does not influence the neurologic and behavioral aspects of LND. Despite treatment from birth for uric acid elevation, behavioral and neurologic symptoms are unaffected. The most significant complications of LND are renal failure and self-mutilation.

Treatment

Medical management of LND focuses on prevention of renal failure by pharmacologic treatment of hyperuricemia, with high fluid intake along with alkalization and allopurinol (or more often febuxostat). A low-purine diet and reduced fructose intake are desirable.

Allopurinol treatment must be monitored because urinary oxypurine excretion with all overproduction disorders is sensitive to allopurinol, resulting in an increased urine concentration of xanthine, which is extremely insoluble. Self-mutilation is reduced through behavior management and the use of restraints and/or removal of teeth. Pharmacologic approaches to decrease anxiety and spasticity with medication have mixed results. Drug therapy focuses on symptomatic management of anticipatory anxiety, mood stabilization, and reduction of self-injurious behavior. Although there is no standard drug treatment, diazepam may be helpful for anxiety symptoms, risperidone for aggressive behavior, and carbamazepine or gabapentin for mood stabilization. Each of these medications may reduce SIB by helping to reduce anxiety and stabilize mood. *S* -adenosylmethionine (**SAMe**), which is thought to act by countering nucleotide depletion in the brain, has been reported specifically to reduce the rate of self-injury in some cases. Animal studies have suggested that D1-dopamine receptor antagonists such as ecopipam may suppress SIB. Despite limited data, the drug appears to reduce SIB in most patients, suggesting further study to establish an appropriate dosing regimen and assess toxicity.

Several patients have received **bone marrow transplantation** (BMT), based on the hypothesis that the central nervous system (CNS) damage is produced by a circulating toxin. There is no evidence that BMT is a beneficial treatment approach; it remains an experimental and potentially dangerous therapy. Two patients received partial exchange transfusions every 2 mo for 3-4 yr. Erythrocyte HPRT activity was 10–70% of normal during this period, but no reduction of neurologic or behavioral symptoms was apparent. Successful preimplantation genetic diagnosis and in vitro fertilization for LND has been reported with the birth of an unaffected male infant.

Both the motivation for self-injury and its biologic basis must be addressed in treatment programs. However, behavioral techniques alone, using operant conditioning approaches, have not proved to be an adequate general treatment. Although **behavioral procedures** have had some selective success in reducing self-injury, difficulty with generalization outside the experimental setting limits this approach, and patients under stress may revert to their previous SIB. Behavioral approaches may also focus on reducing SIB through treatment of phobic anxiety associated with being unrestrained. The most common techniques are systematic desensitization, extinction, and differential reinforcement of other (competing) behavior. Stress management has been recommended to assist patients to develop more effective coping mechanisms. Individuals with LND do not respond to contingent electric shock or similar aversive behavioral measures. An increase in self-injury may be observed when aversive methods are used.

Restraint (day and night) and dental procedures are common means to prevent self-injury. The time in restraints is linked to the age of onset of self-injury. Children with LND can participate in making decisions regarding restraints and the type of restraints. The time in restraints may potentially be reduced with systematic behavior treatment programs. Many patients have teeth extracted to prevent self-injury. Others use a protective mouth guard designed by a dentist. Most parents suggest that stress reduction and awareness of the patient's needs are the most effective in reducing self-injury. Positive behavioral techniques of reinforcing appropriate behavior are rated effective by almost half the families.

Deep brain stimulation to the anteroventral internal globus pallidus is a procedure that has successfully treated self-injury and lessened dystonia in several case reports.

Adenine Phosphoribosyltransferase Deficiency (Dihydroxyadeninuria)

APRT, a purine salvage enzyme, catalyzes the synthesis of AMP from adenine and 5-phosphoribosyl-1-pyrophosphate (PP-ribose-P). The absence of this enzyme results in the cellular accumulation of adenine and it being oxidized as an alternative substrate by xanthine dehydrogenase to form **2,8-dihydroxyadenine** , which is extremely insoluble. APRT deficiency is present from birth, becoming apparent as early as 5 mo and as late as the 7th decade.

Genetics

The disorder is an autosomal recessive trait with considerable clinical heterogeneity. The *APRT* gene is located on chromosome 16q (16q24.3) and encompasses 2.8 kb of genomic DNA.

Clinical Manifestations

These include urinary calculus formation with crystalluria, urinary tract infections, hematuria, renal colic, dysuria, and acute renal failure. Brownish spots on the infant's diaper or yellow-brown crystals in the urine suggest the diagnosis. The 2,8-dihydroxyadenine is cleared efficiently by the kidneys and so does not accumulate in plasma, but precipitates readily in the renal lumen.

Laboratory Findings

Urinary levels of adenine, 8-hydroxyadenine, and 2,8-dihydroxyadenine are elevated, whereas plasma uric acid is normal. The deficiency may be complete (**type I**) or partial (**type II**); the partial deficiency is reported in Japan. The diagnosis is made based on the level of residual enzyme in erythrocyte lysates. The renal calculi, composed of 2,8-dihydroxyadenine, are radiolucent, soft, and easily crushed. These stones are not distinguishable from uric acid stones by routine tests but require high-performance liquid chromatography (HPLC), ultraviolet (UV) light, infrared light, mass spectrometry, x-ray crystallography, or capillary electrophoresis for diagnosis, particularly to distinguish from stones in HPRT deficiency.

Treatment

Treatment includes high fluid intake, dietary purine restriction, and allopurinol, which inhibits the conversion of adenine to its metabolites and prevents further stone formation. Alkalinization of the urine is to be avoided, because unlike that of uric acid, the solubility of 2,8-dihydroxyadenine does not increase up to pH 9. **Shock wave lithotripsy** has been reported to be successful. The **prognosis** depends on renal function at diagnosis. Early treatment is critical in the prevention of stones because severe renal insufficiency may accompany late recognition.

Disorders Linked to Purine Nucleotide Synthesis

Phosphoribosylpyrophosphate Synthetase Superactivity and Deficiency

Phosphoribosylpyrophosphate (**PRPP**) is a substrate involved in the synthesis of essentially all nucleotides and important in the regulation of the de novo pathways of purine and pyrimidine nucleotide synthesis. The synthetase enzyme (**PRPS**) produces PRPP from ribose-5-phosphate and ATP (see Figs. 108.1 and 108.2). PRPP is the first intermediary compound in the de novo synthesis of purine nucleotides that lead to the formation of inosine monophosphate, then to ATP and GTP.

Genetic disorders of this enzyme affect only the PRPS-1 isoform; PRPS-2 mutations have not been described. PRPS-1 disorders are all X-linked and are divided into "superactivity," which occurs as 2 phenotypes (infantile or early childhood onset, and a milder form with late-juvenile or early-adult onset), and "deficiency," which is a spectrum disorder that is distinguished clinically according to severity as 3 disorders: Arts syndrome, Charcot-Marie-Tooth disease X-linked-5, and X-linked deafness-2.

Superactivity of the enzyme results in an increased generation of PRPP in dividing cells. Because PRPP aminotransferase, the first enzyme of the purine de novo pathway, is not physiologically saturated by PRPP, the synthesis of purine nucleotides increases, and consequently the production of uric acid is increased. PRPP synthetase superactivity is one of the few hereditary disorders in which the activity of an enzyme is enhanced. The infantile or early childhood form of PRPS-1 superactivity has severe neurologic consequences accompanied by uric acid overproduction, whereas individuals with the late-juvenile or early-adult presentation are neurologically normal but still have uric acid overproduction.

Deficiency of PRPS-1 produces depleted purine nucleotide synthesis in tissues dependent on PRPS-1, which includes brain as well as other neural tissues and lung.

Genetics

Three distinct complementary DNAs for PRPS have been cloned and sequenced. Two forms, PRPS-1 and PRPS-2, are X-linked to Xq22-q24 and Xp22.2-p.22.3 (escapes X inactivation), respectively, and are widely expressed. The 3rd locus maps to human chromosome 7 and appears to be transcribed only in the testes. PRPS-1 defects are thus inherited as X-linked traits and present with varying degrees of severity. The **late-onset** form of superactivity arises from increased transcription of normal messenger RNA; the cause of this has not been discovered. The **early-onset** form of superactivity arises from mutations affecting allosteric regulation of the protein that controls feedback inhibition by inorganic phosphate and dinucleotides. At the same time, these mutations destabilize the protein, so that in slow or nonreplicating cells, such as neurons and red blood cells (RBCs), the enzyme becomes inactive. In contrast, the deficiency phenotypes of PRPS-1 are produced by mutations directly affecting enzyme function, usually in the substrate binding site. Even though the defect is X-linked, it should be considered in a child or young adult of either sex with hyperuricemia and/or hyperuricosuria and normal HPRT activity in lysed RBCs.

Clinical Manifestations

Affected hemizygous males with early-onset superactivity show signs of uric acid overproduction that are apparent in infancy or early childhood, as well as psychomotor delay and sensorineural deafness. Hypotonia, ataxia, and autistic-like behavior have been described. Heterozygous female carriers may also develop gout and hearing impairment. The late-onset type is found in males who show only hyperuricemia and hyperuricosuria, but no neurologic signs. The mildest form of PRPS-1 deficiency manifests as progressive postlingual hearing loss in **X-linked deafness-2** (DFN2). More severe mutations constitute the **Charcot-Marie-Tooth disease X-linked-5** phenotype, which includes peripheral neuropathy, hearing impairment, and optic atrophy. The most severe PRPS-1 mutations occur in patients with **Arts syndrome** , who also have central neuropathy and an impaired immune system. Females appear to be unaffected, but hemizygous males have usually not survived beyond the 1st decade, typically succumbing to lung disease. SAMe therapy has prolonged survival, although the neurologic deficits, including the deafness, do not appear to be responsive.

A mechanism for the neurologic symptoms is not yet known, but it can be hypothesized that nucleotide depletion is present in neural tissues, including the brain. Abnormalities of hearing and vision are typical of PRPS-1 deficiency, where the absence of this enzyme presumably compromises these highly energy-dependent neural functions. The high transcript level of PRPS-1 in lung and bone marrow also suggests that its absence may be causal for the recurrent lung infections that characterize Arts syndrome.

Laboratory Findings

For PRPS-1 “superactivity” (both juvenile and adult presentations), serum uric acid may be grossly raised and the urinary excretion of uric acid increased. For PRPS “deficiency,” uric acid is normal, not low, probably because PRPS-2 provides the major uric acid–forming activity in liver and other major organs.

Diagnosis requires that PRPS-1 activity be measured in erythrocytes and cultured fibroblasts. The adult superactivity disorder must be differentiated from partial HPRT deficiency involving the salvage pathway, which also presents with mild or absent neurologic traits accompanied by hyperuricemia.

Treatment

Treatment of PRPS deficiency, specifically Arts syndrome, has involved mainly experimental therapy with SAMe, as a dietary supplement to correct the depletion of purines. Dietary purines are usually not absorbed into the body but are degraded to uric acid by the gut. SAMe supplementation (beginning at 20 mg/kg/day orally) has been effective in greatly reducing the acute hospitalization episodes of 2 brothers with Arts syndrome, over a period of 10 yr. Treatment of PRPS superactivity is aimed at controlling the hyperuricemia with allopurinol, which inhibits xanthine oxidase, the last enzyme of the purine catabolic pathway. Uric acid production is reduced and is replaced by hypoxanthine, which is more soluble, and xanthine. The initial dose of allopurinol is 10-20 mg/kg/24 hr in children and is adjusted to maintain normal uric acid levels in plasma. The risk of xanthine stone formation is similar to that described for LND. A low-purine diet (free of organ meats, dried beans, and sardines), high fluid intake, and alkalinization of the urine to establish a urinary pH of 6.0-6.5 are necessary. These measures control the hyperuricemia and urate nephropathy but do not affect the neurologic symptoms. There is no known treatment for the neurologic complications.

Adenylosuccinase Lyase Deficiency (Succinylpurinuria)

Adenylosuccinase lyase deficiency is an inherited deficiency of de novo purine synthesis in humans. Adenylosuccinase lyase is an enzyme that catalyzes 2 pathways in de novo synthesis and purine nucleotide recycling. These are the conversion of succinylaminoimidazole carboxamide ribotide (SAICAr) into aminoimidazole carboxamide ribotide (AICAR) in the de novo synthesis of purine nucleotides and the conversion of adenylosuccinate (S-AMP) into AMP, the 2nd step in the conversion of inosine monophosphate (IMP) into AMP, in the purine nucleotide cycle. Adenylosuccinase lyase deficiency results in the accumulation in urine, CSF, and to a smaller extent in plasma, of SAICAr and succinyladenosine (S-Ado), the dephosphorylated derivatives of SAICAr and S-AMP, respectively.

Genetics

Succinylpurinuria is an autosomal recessive disorder; the gene has been mapped to chromosome 22q13.1-q13.2, and approximately 50 gene mutations have been identified. Laboratory investigations show grossly raised succinylpurines in urine and CSF, which are normally undetectable.

Clinical Manifestations

The fatal **neonatal** form presents with lethal encephalopathy. Clinical manifestations include varying degrees of psychomotor retardation, generally accompanied by a seizure disorder and autistic-like behaviors (poor eye contact and repetitive behaviors). Neonatal seizures and a severe infantile epileptic encephalopathy are often the first manifestations of this disorder. Others demonstrate moderate to severe intellectual disability, sometimes associated with growth retardation and muscle hypotonia. One female tested in the mild range of intellectual disability. The form of adenylosuccinase lyase deficiency with profound intellectual disability has been designated **type I** and the variant case with mild intellectual disability **type II** . Other patients have an intermediate clinical symptom pattern with moderately delayed psychomotor development, seizures, stereotypies, and agitation.

Pathology

CT and MRI of the brain may show hypotrophy or hypoplasia of the cerebellum, particularly the vermis. It is proposed that rather than being caused by purine nucleotide depletion, the symptoms are from the neurotoxic effects of accumulating succinylpurines. The S-Ado: SAICAr ratio has been linked to phenotype severity, suggesting that SAICAr is the more toxic compound and that S-Ado might be neuroprotective.

The laboratory diagnosis is based on the presence in urine and CSF of SAICAr and S-Ado, both normally undetectable.

Treatment

No successful treatment has been demonstrated for adenylosuccinase lyase deficiency. SAMe supplementation therapy was tested for 6 mo for an infant diagnosed in the early postnatal period, but no amelioration of symptoms was noted, providing further evidence that the disorder arises from nucleotide toxicity rather than depletion. Prenatal diagnosis has been reported. Systematic screening is suggested in infants and children with unexplained psychomotor retardation or seizure disorder.

Aminoimidazole Carboxamide Ribotide (AICAR) Transformylase/Inosine Monophosphate (IMP) Cyclohydrolase Deficiency

AICA riboside is the dephosphorylated product of AICAR, also termed *ZMP*. Along with its di- and triphosphates, ZMP accumulates in RBCs and fibrocytes in inherited deficiency of the bifunctional enzyme AICAR transformylase/IMP cyclohydrolase (**ATIC**), which catalyzes the conversion of AICAR to formyl-AICAR.

Genetics

This inborn error of purine biosynthesis is caused by a mutation of the *ATIC* gene effecting AICAR transformylase activity. In a single reported case, AICAR transformylase was profoundly deficient, whereas the IMP cyclohydrolase level was 40% of normal.

Clinical Features

The disorder is described in a female infant with profound intellectual disability, epilepsy, dysmorphic features (prominent forehead and metopic suture, brachycephaly, wide mouth with thin upper lip, low-set ears, and prominent clitoris because of fused labia minora), and congenital blindness.

Laboratory Findings

Urinary screening with the Bratton-Marshall test to detect AICA resulted in the identification of this disorder. The transformylase was found to be deficient in fibroblasts, confirming diagnosis of ATIC deficiency.

Treatment

No successful treatment is described.

Disorders Resulting From Abnormalities in Purine Catabolism

Myoadenylate Deaminase Deficiency (Muscle Adenosine Monophosphate Deaminase Deficiency)

Myoadenylate deaminase is a muscle-specific isoenzyme of AMP deaminase that is active in skeletal muscle. During exercise, the deamination of AMP leads to increased levels of IMP and ammonia in proportion to the work performed by the muscle. Two forms of myoadenylate deaminase deficiency are known: an inherited (**primary**) form that may be asymptomatic or associated with cramps or myalgia with exercise, and a **secondary** form that may be associated with other neuromuscular or rheumatologic disorders.

Clinical Manifestations

Clinical manifestations are typically isolated muscle weakness, fatigue, myalgias following moderate to vigorous exercise, or cramps. Myalgia may be associated with an increased serum creatine kinase level and detectable electromyelographic abnormalities. Muscle wasting or histologic changes on biopsy are absent. The age of onset may be as early 8 mo, with approximately 25% of cases recognized between 2 and 12 yr. The enzyme defect has been identified in asymptomatic family members. Secondary forms of muscle AMP deaminase deficiency have been identified in Werdnig-Hoffmann disease, Kugelberg-Welander syndrome, polyneuropathies, and amyotrophic lateral sclerosis (see Chapter 630.2). The metabolic disorder involves the purine nucleotide cycle. As shown in Fig. 108.2 , the enzymes involved in this cycle are AMP deaminase, S-AMP synthetase, and S-AMP lyase. It is proposed that muscle dysfunction in AMP deaminase deficiency results from impaired energy production during muscle contraction. It is unclear how individuals may carry the deficit and be asymptomatic. In addition to muscle dysfunction, a mutation of liver AMP deaminase has been proposed as a cause of primary gout, leading to overproduction of uric acid.

Genetics

The inherited form of the disorder is an autosomal recessive trait. *AMPD1,* the gene responsible for encoding muscle AMP deaminase, is located on the short arm of chromosome 1 (1p13-21). Population studies reveal that a mutant allele is found at high frequency in white populations, but alternative splicing of the gene can result in removal of the mutation and normal enzyme function. As a result, the disorder is usually screened by performing the forearm ischemic exercise test. The elevation of venous plasma ammonia following exercise that is seen in unaffected individuals is *absent* in AMP deaminase deficiency.

Laboratory Findings

The final diagnosis is made by histochemical or biochemical assays of a muscle biopsy. The primary form is distinguished by the finding of enzyme levels <2% with little or no immunoprecipitable enzyme. Affected individuals are advised to exercise with caution to prevent rhabdomyolysis and myoglobinuria.

Treatment

Although there are no documented fully effective treatments for myoadenylate deaminase deficiency, it has been proposed that enhancing the rate of replenishment of the ATP pool might be beneficial. Using this rationale, treatment with **ribose** (2-60 g/24 hr orally in divided doses) or **xylitol** , which is converted to ribose, has been reported to improve endurance and muscle strength in some patients, but is ineffective in others. Genetic approaches may be feasible in the future for inherited cases, whereas treatment of the underlying condition is essential in secondary cases.

Adenosine Deaminase Deficiency

See Chapter 152.1 .

Purine Nucleoside Phosphorylase Deficiency

See Chapter 152.2 .

Xanthine Oxidoreductase Deficiency (Hereditary Xanthinuria/Molybdenum Cofactor Deficiency)

Xanthine oxidoreductase (XOR) is the catalytic enzyme in the final step of the purine catabolic pathway and oxidizes hypoxanthine to xanthine and xanthine to uric acid. Because XOR exists in 2 forms, xanthine dehydrogenase and xanthine oxidase, the deficiency is also referred to as **xanthine dehydrogenase/xanthine oxidase deficiency** . Xanthine, the immediate precursor of uric acid, is less soluble than uric acid in urine, and deficiency of the enzyme results in xanthinuria. XOR deficiency may occur in isolated form (**xanthinuria type 1**), in a combined form involving XOR and aldehyde oxidase deficiencies (**xanthinuria type II**), or multiple deficiencies of XOR, aldehyde oxidase, and sulfite oxidase (**molybdenum cofactor deficiency**). All 3 forms result in an almost total replacement of uric acid by hypoxanthine and xanthine in urine, while plasma uric acid is very low or undetectable.

Patients with the isolated form can be asymptomatic or can have mild symptoms; renal stones, often not visible on radiography, are a risk for renal damage and may appear at any age, when patients may present with loin pain or renal insufficiency. For type II xanthinuria the clinical presentation is similar to type I, but patients also have aldehyde oxidase deficiency, which has no known clinical attributes. Molybdenum cofactor deficiency arises from inherited deficiency of molybdenum cofactor synthase, which affects all 3 molybdoenzymes; as with isolated sulfite oxidase deficiency, it usually presents with neonatal feeding problems, neonatal seizures, increased or decreased muscle tone, ocular lens dislocation, severe intellectual disability, and death in early childhood. Milder cases have presented with lens dislocation only.

Genetics

The inheritance of all 3 types of xanthinuria is complex and autosomal recessive. Type I results from mutations in the human *XDH* gene located on chromosome 2p22. Type II xanthinuria arises from mutations in the molybdenum cofactor sulfurase gene located on chromosome 18q12.2; this enzyme completes the synthesis of the molybdenum cofactor, which is essential for the activity of both XOR and aldehyde oxidase. Type III xanthinuria (XOR, aldehyde oxidase, and sulfite oxidase deficiencies) can arise from functional mutations in any of 3 genes: *MOCS1* (encoding 2 enzymes for synthesis of the precursor via a bicistronic transcript), *MOCS2* (encoding molybdopterin synthase), or *GPHN* (encoding gephyrin), located at 6p21.2, 5q11.2, and 14q23.3, respectively.

Laboratory Findings

Diagnosis is made initially by measuring plasma and/or urinary concentrations of uric acid. Plasma uric acid is very low or absent (<1 mg/dL). Urinary uric acid is reduced, being replaced by xanthine and hypoxanthine. Type II patients can be distinguished by the absence in urine of methyl-2-pyridone-carboxamide, the product of nicotinamide (niacin) breakdown by aldehyde oxidase. Alternately, type II patients can be distinguished from type I by their inability to oxidize a test dose of allopurinol to oxypurinol via aldehyde oxidase. Molybdenum cofactor deficiency is distinguished by an additional excessive urinary excretion of sulfite and other sulfur-containing metabolites such as sulfocysteine.

Enzyme assay of XOR is not usually offered because it requires jejunal or liver biopsy, because these are the only human tissues that contain appreciable amounts of the enzyme. Sulfite oxidase and the molybdenum cofactor synthase can be measured in liver and fibroblasts. Molecular genetic analysis can be used to confirm diagnosis by searching for functional mutations among the 3 groups of genes.

Treatment

Although isolated deficiency is generally benign, treatment with a diet of low purines and low fructose (which reduces ATP breakdown to xanthine) with increased fluid intake is recommended. Allopurinol is not recommended. The prognosis for molybdenum cofactor deficiency has previously been very poor, but trials of cyclic pyranopterin monophosphate are promising in patients with a defect in the *MOCS1* gene.

Disorders of Pyrimidine Metabolism

The pyrimidines are the building blocks of DNA and RNA and involved in the formation of active intermediates in carbohydrate and phospholipid metabolism (e.g., uridine diphosphate glucose, cytidine diphosphate choline), glucuronidation in detoxification processes (uridine diphosphate), and glycosylation of proteins and lipids.

The essential precursor for pyrimidine biosynthesis is carbamyl-phosphate, which is shared with the urea cycle. Consequently, proximal blockages of the urea cycle results in carbamyl-phosphate overflowing into the pyrimidine pathway. Pyrimidine synthesis differs from that of purines in that the single pyrimidine ring is first assembled to form orotic acid and then linked to ribose phosphate to form the central pyrimidine nucleotide *uridine monophosphate* (UMP). The pyrimidine bases, uracil and thymine, are catabolized in 4 steps (see Fig. 108.3). Eight disorders of pyrimidine metabolism are reviewed. Purine catabolism has an easily measurable end-point in uric acid; however, there is no equivalent compound in pyrimidine catabolism. Disorders of de novo pyrimidine synthesis include hereditary **orotic aciduria** and dihydroorotate dehydrogenase deficiency (**Miller syndrome**). **Thymidine kinase deficiency** is part of pyrimidine salvage, and the other disorders involve overactivity (in one syndrome) or defects in the pyrimidine degradation pathway. Pyrimidine disorders may present as anemia, neuropathologies, acrofacial dysostosis, or multisystem mitochondrial disorders. The first 3 steps of the degradation pathways for thymine and uracil, respectively, make use of the same enzymes (DPD, DPH, and UP). These 3 steps result in the conversion of uracil into β-alanine. There is increasing evidence that pyrimidines play an important role in the regulation of the nervous system. Reduced production of the neurotransmitter function of β-alanine is hypothesized to produce clinical symptoms. Clinically, pyrimidine disorders may be overlooked because they are rare and their symptoms are not highly specific; however, they should be considered as possible causes of anemia and neurologic disease and are a contraindication for treatment of cancer patients with certain pyrimidine analogs.

Uridine Monophosphate Synthase Type 1 Deficiency (Hereditary Orotic Aciduria)

Hereditary orotic aciduria is a disorder of pyrimidine synthesis associated with deficient activity of the last 2 steps of the de novo pyrimidine synthetic pathway: orotate phosphoribosyltransferase and orotidine-5′-monophosphate decarboxylase (ODC). The activities of these 2 steps reside in separate domains of a bifunctional protein, UMP synthase. This catalyzes the 2-step conversion of orotic acid to UMP via orotidine monophosphate. Hereditary orotic aciduria (UMP synthase deficiency) results in the excessive accumulation of orotic acid.

Genetics

UMP synthase deficiency is inherited as an autosomal recessive disorder, with both functional domains encoded on a single gene, *UMPS*, located on the long arm of chromosome 3 (3q13). Theoretically, random mutations in the gene should have equal chances of producing either orotate phosphoribosyltransferase or ODC deficiency, but there has been only a single case of ODC deficiency reported. Genetic metabolic defects that involve 4 of the 6 enzymes associated with the urea cycle may also result in orotic aciduria, secondary to PPRP depletion resulting from a substantial increased flux through the pyrimidine synthesis pathway.

Clinical Manifestations

Patients with hereditary orotic aciduria (UMP synthase type 1 deficiency) have a macrocytic hypochromic megaloblastic anemia unresponsive to usual therapy (iron, folic acid, vitamin B_{12}) and may develop leukopenia. Onset is usually in 1st months of life. Untreated, this disorder can lead to intellectual disability, failure to thrive, cardiac disease, strabismus, crystalluria, and occasional ureteric obstruction. Renal function is generally normal. Heterozygotes may have mild orotic aciduria but are not otherwise affected. The clinical features are thought to be related to pyrimidine nucleotide depletion. Metabolites derived from several pharmacologic agents (e.g., 5-azauridine, allopurinol) can produce secondary orotic aciduria and orotidinuria by specifically inhibiting the ODC step of UMP synthase. Orotic aciduria may also occur in association with parenteral nutrition, essential amino acid deficiency, and Reye syndrome.

Laboratory Findings

The enzymatic defect may be demonstrated in liver, lymphoblasts, erythrocytes, leukocytes, and cultured skin fibroblasts. A carrier detection test is available, as is prenatal diagnosis.

Treatment

The administration of **uridine** in doses of 50-300 mg/kg/day has led to clinical improvement and reduction in orotic acid excretion in UMP synthase type 1 deficiency. Lifelong treatment is required. Uracil is ineffective because, unlike purines, pyrimidine salvage occurs at the nucleoside (uridine) level. The long-term prognosis in uncomplicated cases is good; however, congenital malformations and other associated features may adversely affect outcome.

Dihydroorotate Dehydrogenase Deficiency

(Miller Syndrome)

Miller syndrome was the first mendelian disorder whose molecular basis was identified by whole exome sequencing and shown to correlate with mutations in dihydroorotate dehydrogenase *(DHODH)* . The enzyme DHODH is associated with the mitochondrial electron transport chain and is required for de novo pyrimidine synthesis, catalyzing the oxidation of DHO to orotic acid.

Clinical Manifestations

Miller syndrome is a recognizable **acrofacial dysostosis syndrome** with a combination of craniofacial and limb anomalies. It includes micrognathia, orofacial clefts, malar hypoplasia, aplasia of the medial lower-lid eyelashes, cleft lip/palate, coloboma of the lower eyelid, and cup-shaped ears, combined with postaxial limb deformities, hypoplasia of the limbs with or without ulnar and fibular hypoplasia, and supernumerary nipples. Many of these features are similar to **Treacher Collins syndrome** (see Chapter 337).

Laboratory Findings

Assays of disease-associated *DHODH* alleles predict affected individuals have a deficiency of de novo pyrimidine synthesis, but with significant residual function.

Treatment

Theoretically, dietary supplementation with orotic acid or uridine should bypass the metabolic block. However, because the main effects occur in utero, it is unlikely that the phenotypic abnormality could be corrected.

Dihydropyrimidine Dehydrogenase Deficiency (Thymine-Uraciluria, Pyrimidinuria)

DPD catalyzes the initial and rate-limiting step in the degradation of the pyrimidine bases uracil and thymine. DPD has been identified in most tissues, with the highest activity being in lymphocytes.

Genetics

DPD deficiency is an autosomal recessive disorder, with the *DPYD* gene mapping to chromosome 1p22, with at least 32 polymorphisms detected. It is estimated that the frequency of heterozygosity may be as high as 3%.

Clinical Manifestations

Children may have seizure disorder, intellectual disability and motor delay. Less common features are growth retardation, microcephaly, autistic-like behavior, and ocular anomalies. Others may have milder neurologic symptoms and language disorder. Unaffected individuals have been reported, suggesting possible secondary gene effects. Most patients have an initial period of normal psychomotor development, followed by subsequent developmental delays. Symptoms may be linked to altered uracil, thymine, or β-alanine homeostasis. Because β-alanine is a structural analog of γ-aminobutyric acid and glycine, it has been proposed that it may affect inhibitory neurotransmission. DPD is the initial and rate-limiting enzyme in the inactivation of the antineoplastic drug 5-fluorouracil (5-FU), being responsible for 80% of its catabolism. Patients with partial DPD deficiency are at risk for developing a severe 5-FU–associated toxicity. In adult patients, neurotoxicity (headache, somnolence, visual illusions, memory impairment) linked to pyrimidinemia after 5-FU treatment for cancer is reported in previously healthy individuals.

Laboratory Findings

DPD deficiency is characterized by a variable phenotype and diagnosed by the gross accumulation of thymine and uracil in urine (**thymine-uraciluria**), plasma, and CSF. Uric acid levels have been reported to be normal. Prenatal diagnosis has been reported.

Treatment

There is no established treatment for this disorder, although patients with seizures do respond to anticonvulsant medications. *DPYD* genetic variants associated with partial or complete DPD activity and occurring with relatively high frequency in populations are potentially useful predictive markers of patient response to 5-FU chemotherapy.

Dihydropyrimidinase Deficiency (Dihydropyrimidinuria)

DPH is the 2nd enzyme in the 3-step degradation pathway of uracil and thymine. DPH deficiency is characterized by increased urinary excretion of dihydrouracil and dihydrothymine (**dihydropyrimidinuria**), as well as uracil and thymine. Similar to DPD deficiency, there is a variable clinical phenotype.

Genetics

This is an autosomal recessive disorder, with the *DPYS* gene mapped to chromosome 8q22. One study found no significant difference in residual activity between mutations observed in symptomatic and asymptomatic individuals, again similar to DPD deficiency. Population prevalence in a Japanese sample was 0.1%.

Clinical Manifestations

Clinical manifestations are similar to DPD deficiency, which is evidence that defects in these sequential steps produce a common disorder. Symptoms in 3 unrelated affected cases included seizures with dysmorphic features and developmental delay in 2 patients. However, 3 unrelated infants and 2 adult asymptomatic cases were identified in a screening program for pyrimidine degradation disorders in Japan and were asymptomatic despite the accumulation of pyrimidine degradation products in body fluids.

Laboratory Findings

Organic acid screening may identify increased amounts of uracil and thymine in urine. Oral loading tests with uracil, dihydrouracil, thymine, and dihydrothymine have been used to detect carriers of DPH deficiency. In symptomatic cases, treatment with β-alanine has been attempted with equivocal results. A single case of increased sensitivity to 5-FU has been reported.

Deficiency of β-Ureidopropionase (*N* -Carbamyl-β-Amino Aciduria)

The pyrimidine bases uracil and thymine are degraded via the consecutive action of 3 enzymes to β-alanine and β-aminoisobutyric acid, respectively. The 3rd enzyme in the pathway is **ureidopropionase (UP)** , and its deficiency leads to *N* -carbamyl-β-amino aciduria. 3-Ureidopropionic acid (3-UPA) acts as an endogenous neurotoxin through inhibition of mitochondrial energy metabolism, resulting in the initiation of secondary, energy-dependent excitotoxic mechanisms.

Genetics

Fluorescence in situ hybridization (FISH) localized the human β-ureidopropionase gene, *UPB1*, to 22q11.2.

Clinical Manifestations

These include muscular hypotonia, dystonic movements, seizures, and severe developmental delay. Some individuals with UP deficiency and no neurologic problems have been reported.

Laboratory Findings

Neuropathology involves both gray and white matter. UP deficiency leads to pathologic accumulation of 3-UPA in body fluids. Urinary analysis in a reported case showed elevated levels of *N* -carbamyl-β-alanine and *N* -carbamyl-β-aminoisobutyric acid (ureidoisobutyric acid). The enzyme is expressed only in the liver, and no activity of β-ureidopropionase is detected in a liver biopsy.

Treatment

There is no known treatment for UP deficiency.

Pyrimidine 5′-Nucleotidase Deficiency

Erythrocyte maturation is accompanied by RNA degradation and the release of mononucleotides. Pyrimidine 5′-nucleotidase is the first degradative enzyme of the pyrimidine salvage cycle and catalyzes the hydrolysis of pyrimidine 5′-nucleotides to the corresponding nucleosides. Enzyme deficiency results in the accumulation of high levels of cytidine and uridine nucleotides in the erythrocytes, which in turn results in hemolysis. Deficiency of pyrimidine 5′-nucleotidase may be at least in part compensated in vivo by other nucleotidases or perhaps other nucleotide metabolic pathways.

Genetics

This is an autosomal recessive disorder involving the gene *NT5C3A* on chromosome 7 (7p15).

Clinical Manifestations

Affected patients with pyrimidine 5′-nucleotidase deficiency clinically present with a defect restricted to erythrocytes and characterized by nonspherocytic hemolytic anemia with basophilic stippling. Other characteristic features include splenomegaly, increased indirect bilirubin, and hemoglobinuria. **Lead** is a powerful inhibitor of pyrimidine 5′-nucleotidase, and assessment of lead levels should be included whenever hemolytic anemia, pyrimidine 5′-nucleotidase deficiency, and basophilic stippling are found together.

Laboratory Findings

Diagnosis requires assay of erythrocyte UMP hydrolysis to form uridine and inorganic phosphate. The enzyme defect should be suspected in patients with nonspherocytic hemolytic anemia with basophilic stippling. The anemia is usually moderate, and transfusions are rarely necessary.

Treatment

There is no specific treatment. Splenectomy has not proved to be effective. Lead-induced acquired pyrimidine 5′ nucleotidase deficiency is treatable, unlike the congenital deficiency.

Overactive Cytosolic 5′-Nucleotidase (Pyrimidine Nucleotide Depletion)

Pyrimidine nucleotide depletion and overactive cytosolic 5′-nucleotidase, may lead to a neurodevelopmental disorder. Four unrelated patients showed 6-10–fold elevation in the activity of pyrimidine 5′-nucleotidase in fibroblasts with both purine and pyrimidine substrates. Investigation in cultured fibroblasts derived from these patients showed normal incorporation of purine bases into nucleotides but decreased incorporation of uridine and orotic acid.

Clinical Manifestations

These include developmental delay, seizures, ataxia, recurrent infections, severe language deficit, hyperactivity, short attention span, and aggressive behavior appearing within the 1st few years of life. Affected patients show electroencephalogram abnormalities. Metabolic testing is normal except for persistent hypouricosuria. It is proposed that increased catabolic activity and decreased pyrimidine salvage cause a deficiency of pyrimidine nucleotides.

Treatment

Treatment is with oral uridine based on compensating for the increased nucleotide catabolism. All reported patients treated with uridine showed improved speech and behavior, decreased seizure activity with discontinuation of seizure medications, and decreased infections.

Thymidine Phosphorylase Deficiency (Mitochondrial Neurogastrointestinal Encephalomyopathy)

Thymidine phosphorylase catalyzes the catabolism of thymidine to thymine. This enzyme is also known as *platelet-derived endothelial cell growth factor* because of its angiogenic properties, or *gliostatin*, indicating its inhibitory effects on glial cell proliferation. It has been implicated in mitochondrial nucleoside metabolism. Plasma thymidine level is increased more than 20-fold in patients compared to controls. Loss of function of thymidine phosphorylase causes **mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)** , which is inherited as a single autosomal recessive disorder, causing mitochondrial DNA depletion and instability. In MNGIE, loss of thymidine phosphorylase activity causes toxic accumulations of the nucleosides thymidine and deoxyuridine, which are phosphorylated to the corresponding nucleoside triphosphate in the mitochondrion, leading to mitochondrial deoxynucleoside triphosphate pool imbalances and aberrant mitochondrial DNA replication.

Genetics

The *TYMP* gene encoding thymidine phosphorylase has been identified as the *MNGIE* gene and is mapped to chromosome 22q13.32-qter, but the protein is imported into mitochondria.

Clinical Manifestations

Clinical manifestations of MNGIE usually begin in adolescence and young adulthood and include ptosis, progressive external ophthalmoparesis, GI dysmotility (pseudoobstruction) and malabsorption, cachexia, peripheral neuropathy, skeletal muscle myopathy, and leukoencephalopathy.

Laboratory Findings

Muscle biopsies typically reveal mitochondrial abnormalities. Screening is performed by detection of grossly raised thymidine and deoxyuridine in urine and plasma, which are normally absent. Confirmation of the diagnosis can be made by assay of thymidine phosphorylase activity in peripheral leukocytes. Molecular genetic analysis will show functional mutations in the *TYMP* gene. Increased thymidine and/or deoxyuridine nucleotides may cause mitochondrial nucleotide pool imbalance, resulting in mitochondrial DNA alterations, in particular DNA depletion.

Treatment

Supportive treatment is indicated. There is no established therapy for MNGIE; bone marrow transplantation has been performed on several patients, but no improvement in symptoms or disease progression has been reported. Allogeneic hematopoietic stem cell transplantation to restore thymidine phosphorylase activity and eliminate toxic metabolites is a potential therapy for MNGIE.

Thymidine Kinase 2 Deficiency

Thymidine kinase 2 (TK2) is a key enzyme for the pyrimidine salvage pathway to provide precursor nucleotide for mitochondrial DNA. TK2 deficiency causes tissue-specific depletion of mitochondrial DNA. TK2 normally phosphorylates thymidine and deoxycytidine.

Genetics

The TK2 gene is located on chromosome 16q 22; the deficiency is inherited in an autosomal recessive manner.

Clinical Manifestations

Affected individuals with TK2 deficiency have severe myopathy and depletion of muscular mitochondrial DNA in infancy.

Treatment

No specific treatment is available. Supportive treatment is indicated.

CHAPTER 109

Hutchinson-Gilford Progeria Syndrome (Progeria)

Leslie B. Gordon

Hutchinson-Gilford progeria syndrome (HGPS), or progeria, is a rare, fatal, autosomal dominant segmental premature aging disease. With an estimated incidence of 1 in 4 million live births and prevalence of 1 in 20 million living individuals, there are an estimated total of 400 children living with progeria in 2018 worldwide. There is no gender, ethnic, or regional bias.

Progeria is caused by a single-base mutation in the *LMNA* gene, which results in the production of a mutant lamin A protein called **progerin** . Lamin A is an intermediate filament inner nuclear membrane protein found in most differentiated cells of the body. Without progerin-specific treatment, children with progeria develop **premature progressive atherosclerosis** and die of heart failure, usually between ages 5 and 20 yr. Progerin is found in increased concentration in skin and the vascular wall of normal older individuals compared to younger individuals, suggesting a role in normal aging.

Clinical Manifestations

Children develop the appearance of accelerated aging, but both clinical and biologic overlaps with aging are segmental, or partial. Physical appearance changes dramatically each year that they age (Fig. 109.1). The descriptions discussed next are roughly in order of clinical appearance.

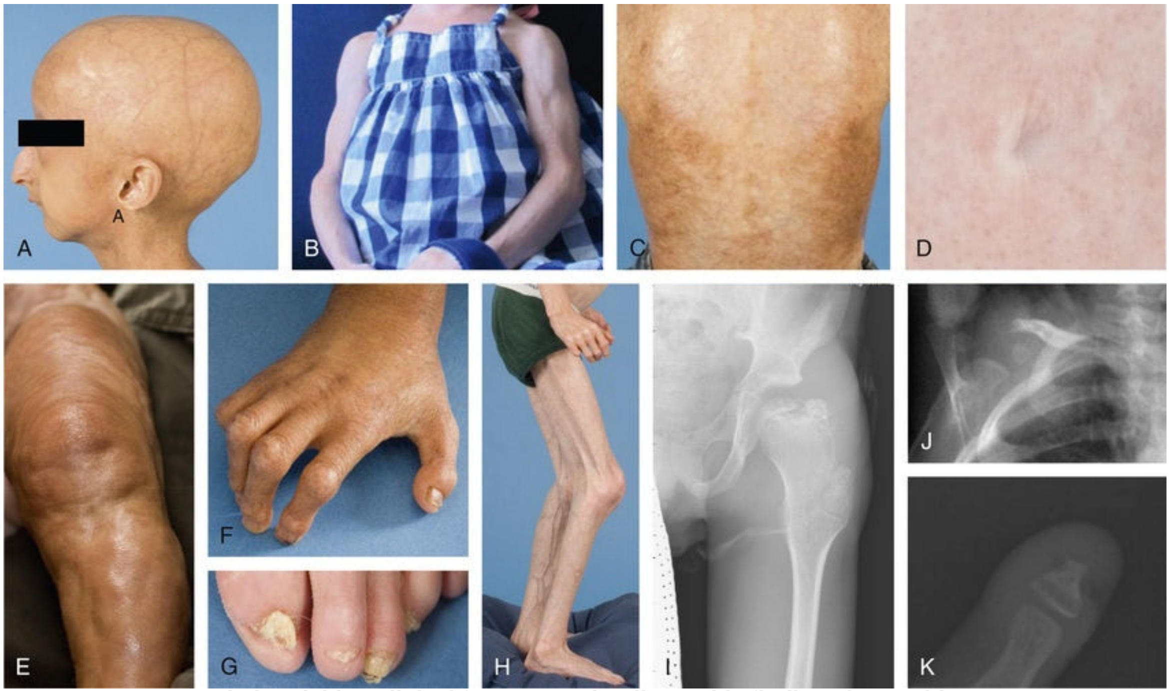

FIG. 109.1 Distinguishing clinical features and radiographic findings in Hutchinson-Gilford progeria syndrome. A, Alopecia, prominent scalp veins, narrowed nasal bridge, retrognathia; B, generalized lipoatrophy leaves muscular prominence; C, skin tightening and mottling; D, flat umbilicus with scarred-over appearance; E, skin bulging; F, digital joint contractures; G, nail dystrophy with spooning; H, knee joint contractures, lipodystrophy; I, coxa valga of the hip; J, clavicular osteolysis; K, acroosteolysis in a thumb. (Photos courtesy of The Progeria Research Foundation and Boston Children's Hospital.)

Dermatologic Changes

Skin findings are often apparent as initial signs of progeria. These are variable in severity and include areas of discoloration, stippled pigmentation, tightened areas that can restrict movement, and areas of the trunk or legs where small (1-2 cm), soft, bulging skin is present. Although usually born with normal hair presence, cranial hair is lost within the first few years, leaving soft, downy, sparse immature hair on the scalp, no eyebrows, and scant eyelashes. Nail dystrophy occurs later in life.

Failure to Thrive

Children with progeria experience apparently normal fetal and early postnatal development. Between several months and 1 yr of age, abnormalities in growth and body composition are readily apparent. Severe failure to thrive ensues, heralding generalized lipoatrophy, with apparent wasting of limbs, circumoral cyanosis, and prominent veins around the scalp, neck, and trunk. The mean weight percentile is usually normal at birth, but decreases to below the 3rd percentile despite adequate caloric intake for normal growth and normal resting energy expenditure. A review of 35 children showed an average weight increase of only 0.44 kg/yr, beginning at 24 mo of age and persisting through life. There is interpatient variation in weight gain, but the projected weight gain over time in individual patients is constant, linear, and very predictable; this sharply contrasts with the parabolic growth pattern for normal age- and gender-matched children. Children reach an average final height of approximately 1 meter and weight of approximately 15 kg. Head circumference is normal. The weight deficit is more pronounced than the height deficit and, associated with the loss of subcutaneous fat, results in the emaciated appearance characteristic of progeria. Clinical problems caused by the lack of subcutaneous fat include sensitivity to cold temperatures and foot discomfort caused by lack of fat cushioning. Overt diabetes is very unusual in progeria, but about 30–40% of children have insulin resistance.

Ocular Abnormalities

Ophthalmic signs and symptoms are caused in part by tightened skin and a paucity of subcutaneous fat around the eyes. Children often experience hyperopia and signs of ocular surface disease from nocturnal lagophthalmos and exposure keratopathy, which in turn may lead to corneal ulceration and scarring. Some degree of photophobia is common. Most patients have relatively good acuity; however, advanced ophthalmic disease can be associated with reduced acuity. *Children with progeria should have an ophthalmic evaluation at diagnosis and at least yearly thereafter.* Aggressive ocular surface lubrication is recommended, including the use of tape tarsorrhaphy at night.

Craniofacial and Dental Phenotypes

Children develop craniofacial disproportion, with micrognathia and retrognathia caused by mandibular hypoplasia. Typical oral and dental manifestations include hypodontia, delayed tooth eruption, severe dental crowding, ogival palatal arch, ankyloglossia, presence of median sagittal palatal fissure, and generalized gingival recession. Eruption may be delayed for many months, and primary teeth may persist for the duration of life. Secondary teeth are present but may or may not erupt. They sometimes erupt on the lingual and palatal surfaces of the mandibular and maxillary alveolar ridges, rather than in place of the primary incisors. In some, but not all cases, extracting primary teeth promotes movement of secondary teeth into place.

Bone and Cartilaginous Abnormalities

Development of bone structure and bone density represents a unique skeletal dysplasia that is not based in malnutrition. Acroosteolysis of the distal phalanges, distal clavicular resorption, and thin, tapered ribs are early signs of progeria (as early as 3 mo of age). *Facial disproportion a narrowed nasal bridge and retrognathia makes intubation extremely difficult, and fiberoptic intubation is recommended.* A pyriform chest structure and small clavicles can lead to reducible glenohumeral joint instability. Growth of the spine and bony pelvis are normal. However, dysplastic growth of the femoral head and neck axis result in coxa valgus (i.e., straightening of the femoral head-neck axis >125 degrees) and coxa magna, where the diameter of the femoral head is disproportionately large for the acetabulum, resulting in hip instability. The resulting hip dysplasia can be progressive and may result in osteoarthritis, avascular necrosis, hip dislocation, and inability to bear weight. Other changes to the appendicular skeleton include flaring of the humeral and femoral metaphyses and constriction of the radial neck. Growth plate morphology is generally normal but can be variable within a single radiograph. The appearance of ossification centers used to define bone age is normal. Bone structure assessed by peripheral quantitative computed tomography (pQCT) of the radius demonstrates distinct and severe abnormalities in bone structural geometry, consistent with progeria representing a *skeletal dysplasia.* Areal bone mineral density (aBMD) *z* scores measured by dual-energy X-ray absorptiometry (DXA) adjusted for height-age, and true (volumetric) BMD assessed by pQCT are normal to mildly reduced, refuting the assumption that patients with progeria are osteoporotic. Fracture rates in progeria are normal and not associated with fragility fractures observed in other pediatric metabolic bone diseases, such as osteogenesis imperfecta.

Contractures in multiple joints (e.g., fingers, elbows, hips, knees, ankles) may be present at birth and may progress with age because of changes in the laxity of the surrounding soft tissue structures (joint capsule, ligament, skin). Along with irregularities in the congruency of articulating joint surfaces, these changes serve to limit joint motion and affect the pattern of gait. Physical therapy is recommended routinely and throughout life to maximize joint function.

Hearing

Low-tone conductive hearing loss is pervasive in progeria and indicative of a stiff tympanic membrane and/or deficits in the middle ear bony and ligamentous structures. Overall, this does not affect ability to hear the usual spoken tones, but preferential classroom seating is recommended, with annual hearing examinations.

Cardiovascular Disease

Approximately 80% of progeria deaths are caused by heart failure, possibly precipitated by events such as superimposed respiratory infection or surgical intervention. Progeria is a **primary vasculopathy** characterized by pervasive accelerated vascular stiffening, followed by large- and small-vessel occlusive disease from atherosclerotic plaque formation, with valvular and cardiac insufficiency in later years. Hypertension, angina, cardiomegaly, metabolic syndrome, and congestive heart failure are common end-stage events**.**

A study of transthoracic echocardiography in treatment-naïve patients revealed diastolic left ventricular dysfunction associated with age-related decline in lateral and septal early (E′) diastolic tissue Doppler velocity *z* scores and an increase in the ratio of mitral inflow (E) to lateral and septal E’ velocity *z* scores. Other echocardiographic findings included left ventricular hypertrophy, left ventricular systolic dysfunction, and mitral or aortic valve disease. These tend to appear later in life. Routine carotid ultrasound for plaque monitoring, carotid-femoral pulse wave velocity (PWV_{cf}) measures for vascular stiffening, and echocardiography are recommended.

Cerebrovascular Arteriopathy and Stroke

Cerebral infarction may occur while the child exhibits a normal electrocardiogram. The earliest incidence of stroke occurred at age 0.4 yr. More often strokes occur in the later years. Over the life span, MRI evidence of infarction can be found in 60% of progeria patients, with half of these clinically silent. Both large- and small-vessel disease is found; collateral vessel formation is extensive. Carotid artery blockages are well documented, but infarction can occur even in their absence. A propensity for strokes and an underlying stiff vasculature make maintaining adequate blood pressure through hydration (habitually drinking well) a priority in progeria patients; special care should be taken when considering maintenance of consistent blood pressure during general anesthesia, airplane trips, and hot weather. In addition, 15% of deaths in children with progeria occur from head injury or trauma, including subdural hematoma. This implies an underlying susceptibility to subdural hematoma.

Sexual Development

Females with progeria can develop Tanner Stage II secondary sexual characteristics, including signs of early breast development and sparse pubic hair. They do not achieve Tanner Stage III. Despite minimal to no physical signs of pubertal development and minimal body fat, over half of females experience spontaneous menarche at a median age of 14 yr. Those experiencing menarche vs nonmenstruating females have similar body mass indices, percentage body fat, and serum leptin levels, all of which are vastly below the healthy adolescent population. If bleeding becomes severe, the complete blood count may be decreased, and an oral contraceptive may be used to decrease bleeding severity. Secondary sexual characteristics in males have not been studied. There are no documented cases of reproductive capacity in females or males with progeria.

Normally Functioning Systems

Liver, kidney, thyroid, immune, gastrointestinal, and neurologic systems (other than stroke related) remain intact. Intellect is normal for age, possibly in part from downregulation of progerin expression in the brain by a brain-specific micro-RNA, miRNA-9.

Laboratory Findings

The most consistent laboratory findings are low serum leptin below detectable levels (>90%) and insulin resistance (60%). Platelet count is often moderately high. High-density lipoprotein (HDL) cholesterol and adiponectin concentrations decrease with increasing age to values significantly below normal. Otherwise, lipid panels, high-sensitivity C-reactive protein, blood chemistries, liver and kidney function tests, endocrine test, and coagulation tests are generally normal.

Molecular Pathogenesis

Mutations in the *LMNA* gene cause progeria. The normal *LMNA/C* gene encodes the proteins lamins A and C, of which only lamin A is associated with human diseases. The lamin proteins are the principal proteins of the nuclear lamina, a complex molecular interface located between the inner membrane of the nuclear envelope and chromatin. The integrity of the lamina is central to many cellular functions, creating and maintaining structural integrity of the nuclear scaffold, DNA replication, RNA transcription, organization of the nucleus, nuclear pore assembly, chromatin function, cell cycling, senescence, and apoptosis.

Progeria is almost always a sporadic autosomal dominant disease. There are 2 documented sibling occurrences, both presumably stemming from parental mosaicism, where 1 phenotypically normal parent has germline mosaicism. It is caused by the accelerated use of an alternative, internal splice site that results in the deletion of 150 base pairs in the 3′ portion of exon 11 of the *LMNA* gene. In about 90% of cases, this results from a single C to T transition at nucleotide 1824 that is silent (Gly608Gly) but optimizes an internal splice site within exon 11. The remaining 10% of cases possess 1 of several single-base mutations within the intron 11 splice donor site, thus reducing specificity for this site and altering the splicing balance in favor of the internal splice. Subsequent to all these mutations, translation followed by posttranslational processing of the altered mRNA produces progerin, a shortened abnormal lamin A protein with a 50–amino acid deletion near its C-terminal end. An understanding of the posttranslational processing pathway and how it is altered to create progerin has led to a number of treatment prospects for the disease (Fig. 109.2).

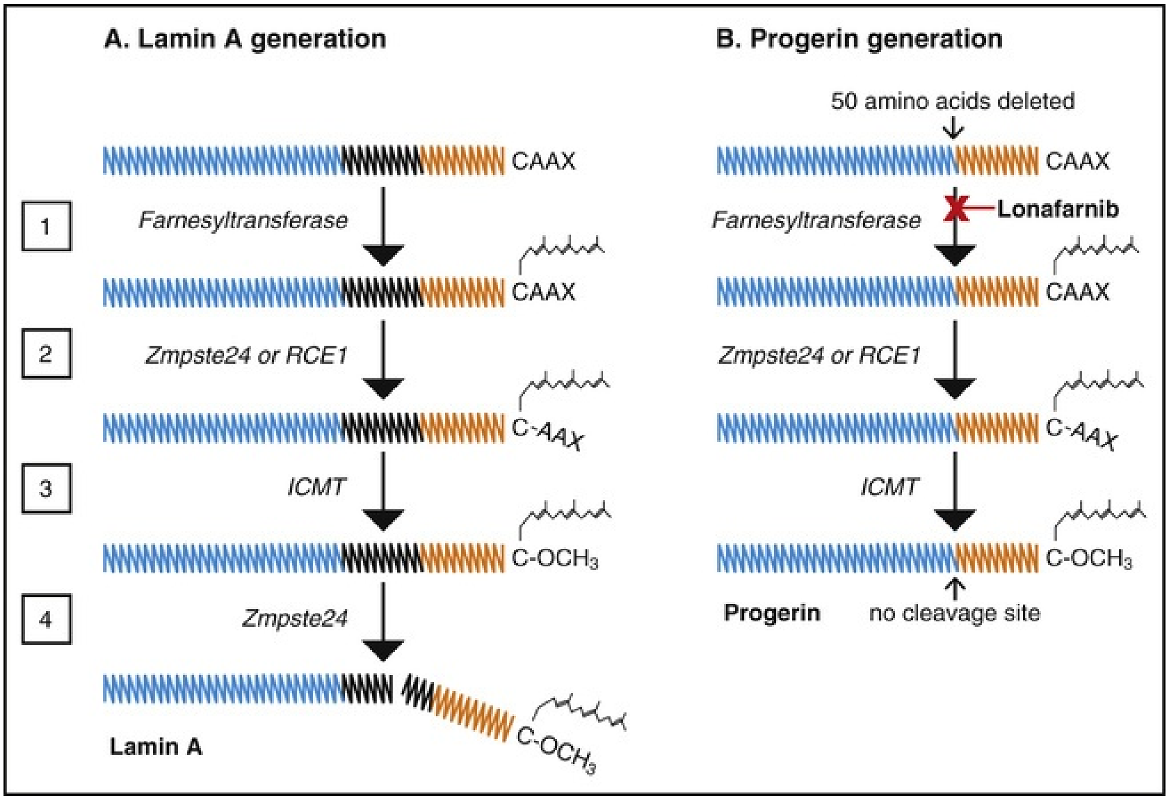

FIG. 109.2 **Posttranslational processing pathways producing lamin A and progerin, including the target site for lonafarnib. A, Prelamin A polypeptide chain, showing its central α-helical rod domain and C-terminal −CAAX box, representing cysteine (C), aliphatic amino acids (AA), and any amino acid (X). The α-helical rod domain is divided into segments that assist in displaying the progerin defect. Posttranslational processing consists of 4 steps: *1,* a farnesyl group is attached to the cysteine residue of the −CAAX box by farnesyltransferase; *2,* the last 3 residues are proteolytically cleaved by the zinc metalloprotease Zmpste24 or Ras-converting enzyme (RCE1); *3,* carboxy-methylation by isoprenyl-cysteine carboxyl methyltransferase (ICMT); and *4,* the terminal 15 C-terminal residues, including the farnesylated and carboxymethylated cysteine, are cleaved off by Zmpste24. B, A 50–amino acid deletion in prelamin A (represented by black segment of the lamin A rod) is the result of a mutation that activates a cryptic splice site within exon 11 of the *LMNA* gene. This deletion leaves progerin without an attachment site for the last processing step—cleavage of the farnesylation and carboxymethylated terminal 15 amino acid residues. Thus, progerin remains farnesylated and intercalated within the inner nuclear membrane, where it causes much of its cellular damage.**

Both lamin A and progerin possess a methylated farnesyl side group attached during posttranslational processing. This is a lipophilic moiety that facilitates intercalation of proteins into the inner nuclear membrane, where most of the lamin and progerin functions are performed. For normal lamin A, loss of the methylated farnesyl anchor releases prelamin from the nuclear membrane, rendering it soluble for autophagic degradation. However, progerin retains its farnesyl moiety. It remains anchored to the membrane, binding other proteins, causing blebbing of the nucleus, disrupting mitosis, and altering gene expression. Progerin also retains a methyl moiety.

Disease in progeria is produced by a dominant negative mechanism; *the action of progerin*, not the diminution of lamin A, causes the disease phenotype. The severity of disease is determined in part by progerin levels, which are regulated by the particular mutation, tissue type, or other factors influencing use of the internal splice site.

Diagnosis and Differential Diagnosis

Overall, the constellation of small body habitus, bone, hair, subcutaneous fat, and skin changes results in the marked physical resemblance among patients with progeria (Fig. 109.3). For this reason, clinical diagnosis can be achieved or excluded with relative confidence even at young ages, even though there have been a few cases of low–progerin-expressing patients with extremely mild signs. Clinical suspicion should be followed by *LMNA* genetic sequence testing. The disorders that resemble progeria are those grouped as the senile-like syndromes and include Wiedmann-Rautenstrauch syndrome, Werner syndrome, Cockayne syndrome, Rothmund-Thomson syndrome, restrictive dermopathy, and Nestor-Guillermo progeria syndrome (Table 109.1). Patients often fall under none of these diagnoses and represent ultra-rare, unnamed progeroid laminopathies that carry either non–progerin-producing mutations in *LMNA* or the lamin-associated enzyme *(ZMPSTE24)* , or progeroid syndromes without lamin-associated mutations.

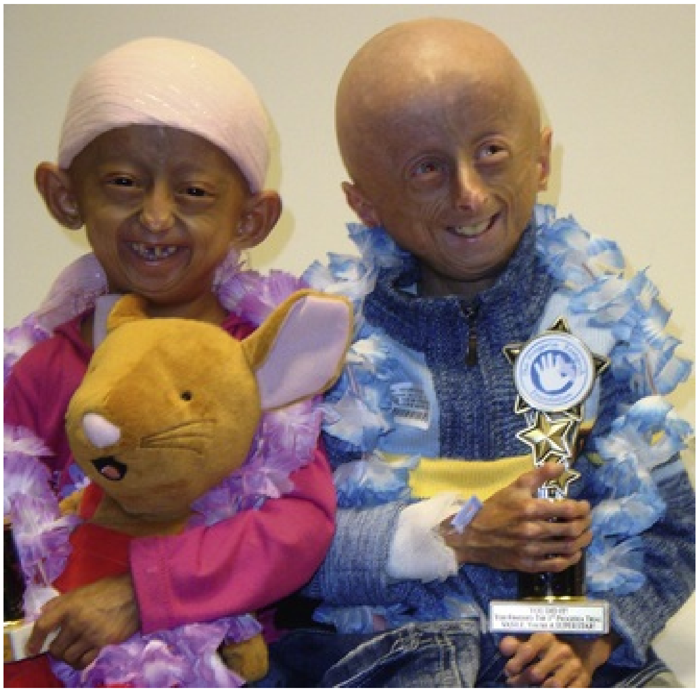

FIG. 109.3 Unrelated 7 yr old female and 10 yr old male with progeria. Appearance is remarkably similar between patients. (Photograph courtesy of The Progeria Research Foundation)

Treatment and Prognosis

Children with progeria develop a severe premature form of atherosclerosis. Prior to death, cardiac decline with left-sided hypertrophy, valvular insufficiency, and pulmonary edema develop; neurovascular decline with transient ischemic attacks (TIAs), strokes, and occasionally seizures can result in significant morbidity. Death occurs generally between ages 5 and 20 yr, with a median life span of 14.5 yr, resulting from heart failure, sometimes with superimposed respiratory infection (approximately 80%); from head injury or trauma, including subdural hematoma (approximately 15%); and rarely from stroke (1–3%) or complications from anesthesia during surgery (1–3%).

Growth hormone , 0.05 mg/kg/day subcutaneously, has resulted in increased rate of weight gain and overall size, but still well below that seen in normal children. Low-dose aspirin therapy is recommended at 2 mg/kg/day, as an extension of what is known about decreasing cardiovascular risk in the general at-risk adult population. It is not known whether growth hormone or low-dose aspirin has any effect on morbidity or mortality.

Several clinical treatment trials have been based on medications that target the posttranslational pathway of progerin (see Fig. 109.2). Inhibiting posttranslational progerin farnesylation is aimed at preventing this disease-causing protein from anchoring to the nuclear membrane, where it carries out much of its damage. A prospective single-arm clinical trial was conducted with the farnesyltransferase inhibitor **lonafarnib** (NCT00425607). Lonafarnib was well tolerated; the most common side effects were diarrhea, nausea, and loss of appetite, which generally improved with time. Subgroups of patients experienced increased rate of weight gain, decreased vascular stiffness measured by decreased PWV_{cf} and carotid artery echodensity, improved left ventricular diastolic function, increased radial bone structural rigidity, improved sensorineural hearing, and early evidence of decreased headache, TIA, and stroke rates. Dermatologic, dental, joint contracture, insulin resistance, lipodystrophy, BMD, and joint contractures were unaffected by drug treatment. A lonafarnib extension study was initiated, which added 30 children to the study. Children treated with lonafarnib demonstrated an increase in estimated survival over untreated children with progeria.

A clinical trial that added *pravastatin* (FDA approved to lower cholesterol) and *zoledronate* (FDA approved for osteoporosis) to the lonafarnib regimen was similarly aimed at inhibiting progerin farnesylation (NCT00916747), but results showed no detected improvements in clinical status over lonafarnib monotherapy. An ongoing clinical trial adding *everolimus* (FDA-approved mTOR inhibitor) to the lonafarnib regimen is aimed at accelerating autophagy of progerin, thus theoretically reducing its accumulation and cellular damage (NCT02579044). Results of this study are forthcoming.

Patient Resources

The **Progeria Research Foundation** (www.progeriaresearch.org) maintains an international progeria patient registry, provides a diagnostics program and complete patient care manual, and coordinates clinical treatment trials. It funds preclinical and clinical research to define the molecular basis of the disorder and to discover treatments and a cure. The Foundation website is an excellent source of current information on progeria for families of children with the disorder, their physicians, and interested scientists. Additional resources include the National Human Genome Research Institute (www.genome.gov/11007255/), National Center for Biotechnology Information Genereviews (www.ncbi.nlm.nih.gov/books/NBK1121/), and National Center for Advancing Translational Sciences (www.rarediseases.info.nih.gov/diseases/7467/progeria).

CHAPTER 110

The Porphyrias

Manisha Balwani, Robert J. Desnick, Karl E. Anderson

Porphyrias are metabolic diseases resulting from altered activities of specific enzymes of the heme biosynthetic pathway. These enzymes are most active in bone marrow and liver. **Erythropoietic porphyrias** , in which overproduction of heme pathway intermediates occurs primarily in bone marrow erythroid cells, usually present at birth or in early childhood with *cutaneous photosensitivity,* or in the case of congenital erythropoietic porphyria, even in utero as nonimmune hydrops. Erythropoietic protoporphyria is the most common porphyria in children and of most interest to pediatricians. Most porphyrias are *hepatic,* with overproduction and initial accumulation of porphyrin precursors or porphyrins in the liver. Activation of hepatic porphyrias is very rare during childhood, reflecting the distinct hepatic regulatory mechanisms for heme biosynthesis that are influenced by pubertal development. Homozygous forms of the hepatic porphyrias may manifest clinically before puberty. Children who are heterozygous for inherited hepatic porphyrias may present with nonspecific and unrelated symptoms, and parents often request advice about long-term prognosis and express concerns about drugs that may exacerbate these conditions.

The DNA sequences and chromosomal locations are established for the genes of the enzymes in this pathway, and multiple disease-related mutations have been found for each porphyria. However, benign variants identified by gene sequencing can be misleading. The inherited porphyrias display autosomal dominant, autosomal recessive, or X-linked inheritance. Although initial diagnosis of porphyria by biochemical methods remains essential, it is especially important to confirm the diagnosis by demonstrating a specific pathogenic gene mutation(s).

The Heme Biosynthetic Pathway

Heme is required for a variety of hemoproteins, such as hemoglobin, myoglobin, respiratory cytochromes, and cytochrome P450 enzymes (CYPs). It is believed that the 8 enzymes in the pathway for heme biosynthesis are active in all tissues. Hemoglobin synthesis in erythroid precursor cells accounts for approximately 85% of daily heme synthesis in humans. Hepatocytes account for most of the rest, primarily for synthesis of CYPs, which are especially abundant in the liver endoplasmic reticulum, and turn over more rapidly than many other hemoproteins, such as the mitochondrial respiratory cytochromes. Pathway intermediates are the porphyrin precursors **δ-aminolevulinic acid** (**ALA** , also known as 5-aminolevulinic acid) and **porphobilinogen (PBG)** , as well as porphyrins (mostly in their reduced forms, known as **porphyrinogens**) (Fig. 110.1). These intermediates do not accumulate in significant amounts under normal conditions or have important physiologic functions.

FIG. 110.1 **Enzymes and intermediates of the heme biosynthetic pathway. The pathway is regulated in the liver by the end product, heme, mainly by feedback repression**

(dashed arrow) .

Altered activity of each enzyme in the pathway has been associated with a specific type of porphyria (Table 110.1). The first enzyme, ALA synthase (ALAS), occurs in 2 forms. An erythroid specific form, ALAS2, is deficient in X-linked sideroblastic anemia, as a result of mutations of the *ALAS2* gene on chromosome Xp11.2. Gain-of-function mutations of *ALAS2* caused by deletions in the last exon cause X-linked protoporphyria (**XLP**), which is phenotypically identical to erythropoietic protoporphyria.

Table 110.1

The Human Porphyrias: Mutations, Time of Presentation, and Tissue- and Symptom-Based Classifications

DISEASE	ENZYME	INHERITANCE	PRESENTATION	Classification*			
				H	E	A/N	C
X-Linked protoporphyria (XLP)	*δ-Aminolevulinate synthase 2 (ALAS2)*	X-linked	Childhood		X		X
δ-Aminolevulinic acid dehydratase porphyria (ADP)	*δ-Aminolevulinic acid dehydratase (ALAD)*	Autosomal recessive	Mostly post puberty	X	X*	X	
Acute intermittent porphyria (AIP)	*Porphobilinogen deaminase (PBGD)*	Autosomal dominant	Post puberty	X		X	
Homozygous AIP		Homozygous dominant	Childhood	X	X	X	
Congenital erythropoietic porphyria (CEP)	*Uroporphyrinogen III synthase (UROS)*	Autosomal recessive	In utero or infancy		X		X
Porphyria cutanea tarda (PCT) type 1	*Uroporphyrinogen decarboxylase (UROD)*	Sporadic	Adults	X			X
PCT type 2 †		Autosomal dominant	Adults	X			X
PCT type 3		Unknown	Adults	X			X
Hepatoerythropoietic porphyria (HEP)		Homozygous dominant	Childhood	X	X*		X
Hereditary coproporphyria (HCP)	*Coproporphyrinogen oxidase (CPOX)*	Autosomal dominant	Post puberty	X		X	X
Homozygous HCP		Homozygous dominant	Childhood	X	X	X	X
Variegate porphyria (VP)	*Protoporphyrinogen oxidase (PPOX)*	Autosomal dominant	Post puberty	X		X	X
Homozygous VP		Homozygous dominant	Childhood	X	X	X	X
Erythropoietic protoporphyria (EPP)	*Ferrochelatase (FECH)*	Autosomal recessive (most commonly heteroallelic with hypomorphic allele)	Childhood		X		X

[*] Classification abbreviations: H, Hepatic; E, Erythropoietic; A/N, Acute/Neurologic; C, Cutaneous.

[†] PCT is a result of inhibition of hepatic UROD. Autosomal dominant inheritance of a partial deficiency of UROD is a predisposing factor in cases defined as familial (type 2) PCT.

ADP and HEP are considered primarily hepatic porphyrias, but substantial increases in erythrocyte zinc protoporphyrin suggest an erythropoietic component.

Regulation of heme synthesis differs in the 2 major heme-forming tissues. Liver heme biosynthesis is primary controlled by the ubiquitous form of ALAS (ALAS1). Synthesis of ALAS1 in liver is regulated by a “free” heme pool (see Fig. 110.1), which can be augmented by newly synthesized heme or by existing heme released from hemoproteins and destined for breakdown to biliverdin by heme oxygenase.

In the erythron, novel regulatory mechanisms allow for the production of the very large amounts of heme needed for hemoglobin synthesis. The response to stimuli for hemoglobin synthesis occurs during cell differentiation, leading to an increase in cell number. Also, unlike the liver, heme has a stimulatory role in hemoglobin formation, and the stimulation of heme synthesis in erythroid cells is accompanied by increases not only in ALAS2, but also by sequential induction of other heme biosynthetic enzymes. Separate erythroid-specific and nonerythroid or “housekeeping” transcripts are known for the first 4 enzymes in the pathway. The separate forms of ALAS are encoded by genes on different chromosomes, but for each of the other three, erythroid and nonerythroid transcripts are transcribed by alternative promoters in the same gene. Heme also regulates the rate of its synthesis in erythroid cells by controlling the transport of iron into reticulocytes.

Intermediates of the heme biosynthetic pathway are efficiently converted to heme and, normally, only small amounts of the intermediates are excreted. Some may undergo chemical modifications before excretion. Whereas the porphyrin precursors ALA and PBG are colorless, nonfluorescent, and largely excreted unchanged in urine, PBG may degrade to colored products such as the brownish pigment called *porphobilin* or spontaneously polymerize to uroporphyrins. Porphyrins are red in color and display bright-red fluorescence when exposed to long-wavelength ultraviolet (UV) light. Porphyrinogens are the reduced form of porphyrins, and are colorless and nonfluorescent, but are readily autoxidized to the corresponding porphyrins when they accumulate or are outside the cell. Only the type III isomers of uroporphyrinogen and coproporphyrinogen are converted to heme (see Fig. 110.1).

ALA and PBG are excreted in urine. Excretion of porphyrins and porphyrinogens in urine or bile is determined by the number of carboxyl groups. Those with many carboxyl groups, such as *uroporphyrin* (octacarboxyl porphyrin) and *heptacarboxyl porphyrin*, are water soluble and readily excreted in urine. Those with fewer carboxyl groups, such as *protoporphyrin* (dicarboxyl porphyrin), are not water soluble and are excreted in bile and feces. *Coproporphyrin* (tetracarboxyl porphyrin) is excreted partly in urine and partly in bile. Because coproporphyrin I is more readily excreted in bile than coproporphyrin III, impaired hepatobiliary function may increase total urinary coproporphyrin excretion and the ratio of these isomers.

Classification and Diagnosis of Porphyrias

Two useful classification schemes reflect either the underlying pathophysiology or the clinical features of porphyrias (see Table 110.1). In **hepatic porphyrias** and **erythropoietic porphyrias** the source of excess production of porphyrin precursors and porphyrins is the liver and bone marrow, respectively. **Acute porphyrias** cause neurologic symptoms that are associated with increases of one or both of the porphyrin precursors, ALA and PBG. In the **cutaneous porphyrias,** photosensitivity results from transport of porphyrins in blood from the liver or bone marrow to the skin. **Dual porphyria** refers to the very rare cases of porphyria with deficiencies of 2 different heme pathway enzymes.

Porphyria cutanea tarda (**PCT**), acute intermittent porphyria (**AIP**), and erythropoietic protoporphyria (**EPP**) are the 3 most common porphyrias, in that order, considering all age-groups, and are very different in clinical presentation, precipitating factors, methods of diagnosis, and effective therapy (Table 110.2). Two less common acute porphyrias, hereditary coproporphyria (**HCP**) and variegate porphyria (**VP**), can also cause blistering photosensitivity (see Table 110.1). Congenital erythropoietic porphyria (**CEP**) causes more severe blistering lesions, often with secondary infection and mutilation. EPP and XLP have the same phenotype and are distinct from the other cutaneous porphyrias in causing nonblistering photosensitivity that occurs acutely after sun exposure. EPP is also the most common porphyria to become manifest before puberty.

Table 110.2

Three Most Common Human Porphyrias and Major

Features

	PRESENTING SYMPTOMS	EXACERBATING FACTORS	MOST IMPORTANT SCREENING TESTS	TREATMENT
Acute intermittent porphyria	Neurologic, adult onset	Drugs (mostly P450 inducers), progesterone, dietary restriction	Urinary porphobilinogen	Hemin, glucose
Porphyria cutanea tarda	Skin blistering and fragility (chronic), adult onset	Iron, alcohol, smoking, estrogens, hepatitis C, HIV, halogenated hydrocarbons	Plasma (or urine) porphyrins	Phlebotomy, low-dose hydroxychloroquine
Erythropoietic protoporphyria	Phototoxic pain and swelling (mostly acute), childhood onset		Total erythrocyte protoporphyrin with metal-free and zinc protoporphyrin	Sun protection

First-Line Laboratory Diagnostic Testing

A few sensitive and specific first-line laboratory tests should be obtained whenever symptoms or signs suggest the diagnosis of porphyria. If a first-line or screening test is significantly abnormal, more comprehensive testing should follow to establish the type of porphyria. Overuse of lab tests for screening can lead to unnecessary expense and even delay in diagnosis. In patients who present with a past diagnosis of porphyria, lab reports that were the basis for the original diagnosis must be reviewed, and if these were inadequate, further testing considered.

Acute porphyria should be suspected in patients with neurovisceral symptoms such as abdominal pain after puberty, when initial clinical evaluation does not suggest another cause. *Urinary PBG* and *total porphyrins* should be measured. Urinary PBG is virtually always increased during acute attacks of AIP, HCP, and VP and is not substantially increased in any other medical conditions. Therefore this measurement is both sensitive and specific. Results from spot (single void) urine specimens are highly informative because very substantial increases are expected during acute attacks of porphyria. A 24 hr collection can unnecessarily delay diagnosis. The same spot urine specimen should be saved for quantitative determination of PBG and total porphyrins (both expressed relative to creatinine) to confirm the qualitative PBG result. ALA is often measured as well, but is usually less elevated than PBG in AIP, HCP, and VP. In ALA dehydratase porphyria, urinary ALA and porphyrins, but not PBG, are greatly elevated. Urinary porphyrins may remain increased longer than porphyrin precursors in some cases of HCP and VP. Measurement of urinary porphyrins alone should be avoided for screening, however, because they are often increased in many disorders other than porphyrias, such as liver diseases, and misdiagnoses of porphyria can result from minimal increases in urinary porphyrins that have no diagnostic significance.

Blistering Cutaneous Porphyrias

Blistering skin lesions caused by porphyria are virtually always accompanied by increases in *total plasma* and *urinary porphyrins*. Porphyrins in plasma in VP are mostly covalently linked to plasma proteins and readily detected by a diagnostic peak in a fluorescence scanning method. The normal range for plasma porphyrins is somewhat increased in patients with end-stage renal disease.

Nonblistering Cutaneous Porphyria

Measurement of total erythrocyte protoporphyrin and, if the total amount is elevated, fractionation of protoporphyrin into its metal-free and zinc-chelated forms, is essential for diagnosis of EPP and XLP. Unfortunately, this is not offered by some major commercial laboratories. Results of zinc protoporphyrin measurements are often recorded (even in the same report) as both *protoporphyrin* and *free erythrocyte protoporphyrin* , with each calculated differently, based on past practices for screening for lead poisoning (which only increases zinc protoporphyrin). Thus the obsolete term *free protoporphyrin* does not mean metal-free protoporphyrin, because it was defined as iron-free protoporphyrin, and dates from before it was known that (except in protoporphyrias) protoporphyrin in erythrocytes is mostly zinc chelated. This unnecessary confusion makes diagnosis and reliable exclusion of protoporphyrias difficult. Total plasma porphyrins are elevated in most but not all cases of protoporphyria, so a normal level should not be relied on to exclude protoporphyria when total erythrocyte protoporphyrin is elevated.

Increases in erythrocyte total and zinc-chelated protoporphyrin occur in many other conditions, including iron deficiency, lead poisoning, hemolysis, anemia of chronic disease, and other erythrocyte disorders. Therefore the diagnosis of EPP must be confirmed by showing a predominant increase in metal-free protoporphyrin. In XLP, both free and zinc protoporphyrin are elevated.

Second-Line Testing

More extensive testing is well justified when a first-line test is positive. For example, a substantial increase in PBG may be caused by AIP, HCP, or VP, and these can be distinguished by measuring erythrocyte porphobilinogen deaminase, urinary porphyrins (using the same spot urine sample), fecal porphyrins, and plasma porphyrins. The various porphyrias that cause blistering skin lesions are differentiated by measuring porphyrins in urine, feces, and plasma. Confirmation at the gene level is important once the diagnosis is established by biochemical testing.

Testing for Subclinical Porphyria

It is often difficult to diagnose or rule out porphyria in patients who had suggestive symptoms months or years in the past, and in relatives of patients with acute porphyrias, because porphyrin precursors and porphyrins may be normal. More extensive testing and consultation with a specialist laboratory and physician may be needed. Before evaluating relatives, the diagnosis of porphyria should be firmly established in an index case, and the lab results reviewed to guide the choice of tests for the family members. The index case or another family member with confirmed porphyria should be retested if necessary. Identification of a disease-causing mutation in an index case greatly facilitates detection of additional gene carriers, because biochemical tests in latent carriers may be normal.

δ-Aminolevulinic Acid Dehydratase Deficient Porphyria

ALA dehydratase deficient porphyria (**ADP**) is sometimes termed *Doss porphyria* after the investigator who described the first cases. The term *plumboporphyria* emphasizes the similarity of this condition to lead poisoning, but incorrectly implies that it is caused by lead exposure.

Etiology

This porphyria results from a deficiency of ALA dehydratase (ALAD), which is inherited as an autosomal recessive trait. Only six cases have been confirmed by mutation analysis. The prevalence of heterozygous ALAD deficiency was estimated to be <1% in Germany and approximately 2% in Sweden.

Pathology and Pathogenesis

ALAD catalyzes the condensation of 2 molecules of ALA to form the pyrrole PBG (see Fig. 110.1). The enzyme is subject to inhibition by a number of exogenous and endogenous chemicals. ALAD is the principal lead-binding protein in erythrocytes, and lead can displace the zinc atoms of the enzyme. Inhibition of erythrocyte ALAD activity is a sensitive index of lead exposure.

Eleven abnormal ALAD alleles, most with point mutations, have been identified, some expressing partial activity, such that heme synthesis is partially preserved. The amount of residual enzyme activity may predict the phenotypic severity of this disease.

ADP is often classified as a hepatic porphyria, although the site of overproduction of ALA is not established. A patient with severe, early-onset disease underwent liver transplantation, without significant clinical or biochemical improvement, which might suggest that the excess intermediates did not originate in the liver. Excess urinary coproporphyrin III in ADP might originate from metabolism of ALA to porphyrinogens in a tissue other than the site of ALA overproduction. Administration of large doses of ALA to normal individuals also leads to substantial coproporphyrinuria. Increased erythrocyte protoporphyrin, as in all other homozygous porphyrias, may be explained by accumulation of earlier pathway intermediates in bone marrow erythroid cells during hemoglobin synthesis, followed by their transformation to protoporphyrin after hemoglobin synthesis is complete. Neurologic symptoms are attributed to neurotoxic effects of ALA, but this is unproven.

Clinical Manifestations

In most cases, symptoms resemble other acute porphyrias, including acute attacks of abdominal pain and peripheral neuropathy. Precipitating factors, such as exposure to harmful drugs, have not been evident in most cases. Four of the reported cases were adolescent males. A Swedish infant had more severe disease, with neurologic impairment and failure to thrive. A 63 yr old man in Belgium developed an acute motor polyneuropathy concurrently with a myeloproliferative disorder.

Laboratory Findings

Urinary ALA, coproporphyrin III, and erythrocyte zinc protoporphyrin are substantially increased. Urinary PBG is normal or slightly increased. Erythrocyte ALAD activity is markedly reduced, and both parents have approximately half-normal activity of this enzyme and normal urinary ALA.

Diagnosis and Differential Diagnosis

The other 3 acute porphyrias are characterized by substantial increases in both ALA and PBG. In contrast, ALA but not PBG is substantially increased in ADP. A marked deficiency of erythrocyte ALAD and half-normal activity in the parents support the diagnosis. Other causes of ALAD deficiency, such as **lead poisoning** , must be excluded. Succinylacetone accumulates in hereditary tyrosinemia type 1 and is structurally similar to ALA, inhibits ALAD, and can cause increased urinary excretion of ALA and clinical manifestations that resemble acute porphyria. Idiopathic acquired ALAD deficiency has been reported. Unlike lead poisoning, the deficient ALAD activity in ADP is not restored by the in vitro addition of sulfhydryl reagents such as dithiothreitol. Even if no other cause of ALAD deficiency is found, it is essential to confirm the diagnosis of ADP by molecular studies.

Treatment

Treatment experience with ADP is limited but is similar to other acute porphyrias. Glucose seems to have minimal effectiveness but may be tried for mild symptoms. **Hemin therapy** was apparently effective for acute attacks in male adolescents, and weekly infusions prevented attacks in 2 of these patients. Hemin was not effective either biochemically or clinically in the Swedish child with severe disease, and it produced a biochemical response but no clinical improvement in the Belgian man with a late-onset form, who had a peripheral neuropathy but no acute attacks. Hemin is also effective in treating porphyria-like symptoms associated with hereditary tyrosinemia and can significantly reduce urinary ALA and coproporphyrin in lead poisoning. Avoidance of drugs that are harmful in other acute porphyrias is advisable. Liver transplantation was not effective in the child with severe disease.

Prognosis

The outlook is generally good in typical ADP cases, although recurrent attacks may occur. The course was unfavorable in the Swedish child with more severe disease and is uncertain in adults with late-onset disease associated with myeloproliferative disorders.

Prevention and Genetic Counseling

Heterozygous parents should be aware that subsequent children are at risk for ADP, as in any autosomal recessive disorder. Prenatal diagnosis is possible but has not been reported.

Acute Intermittent Porphyria

AIP is also termed *pyrroloporphyria, Swedish porphyria,* and *intermittent acute porphyria* and is the most common type of acute porphyria in most countries.

Etiology

AIP results from the deficient activity of the housekeeping form of **porphobilinogen deaminase (PBGD)** . This enzyme is also known as hydroxymethylbilane (HMB) synthase (the prior term, uroporphyrinogen I synthase, is obsolete). PBGD catalyzes the deamination and head-to-tail condensation of 4 PBG molecules to form the linear tetrapyrrole, HMB (also known as preuroporphyrinogen; see Fig. 110.1). A unique dipyrromethane cofactor binds the pyrrole intermediates at the catalytic site until 6 pyrroles (including the dipyrrole cofactor) are assembled in a linear fashion, after which the tetrapyrrole HMB is released. The apo-deaminase generates the dipyrrole cofactor to form the holodeaminase, and this occurs more readily from HMB than from PBG. Indeed, high concentrations of PBG may inhibit formation of the holodeaminase. The product HMB can cyclize nonenzymatically to form nonphysiologic uroporphyrinogen I, but in the presence of the next enzyme in the pathway is more rapidly cyclized to form uroporphyrinogen III.

Erythroid and housekeeping forms of the enzyme are encoded by a single gene on human chromosome 11 (11q24.1→q24.2), which contains 15 exons. The 2 isoenzymes are both monomeric proteins and differ only slightly in molecular weight (approximately 40 and 42 kDa), and result from alternative splicing of 2 distinct messenger RNA (mRNA) transcripts arising from 2 promoters. The housekeeping promoter functions in all cell types, including erythroid cells.

The pattern of inheritance of AIP is autosomal dominant, with very rare homozygous cases that present in childhood. More than 400 *PBGD* mutations, including missense, nonsense, and splicing mutations, and insertions and deletions have been identified in AIP and in many population groups, including blacks. Most mutations are found in only one or a few families. Because of founder effects, however, some are more common in certain geographic areas, such as northern Sweden (W198X), Holland (R116W), Argentina (G116R), Nova Scotia (R173W), and Switzerland (W283X). De novo mutations may be found in approximately 3% of cases. The nature of the *PBGD* mutation does not account for the severity of the clinical presentation, which varies greatly within families. **Chester porphyria** was initially described as a variant form of acute porphyria in a large English family but was found to be caused by a *PBGD* mutation.

Most mutations lead to approximately half-normal activity of the housekeeping and erythroid isozymes and half-normal amounts of their respective enzyme proteins in all tissues of heterozygotes. In approximately 5% of unrelated AIP patients, the housekeeping isozyme is deficient, but the erythroid-specific isozyme is normal. Mutations causing this variant are usually found within exon 1 or its 5′ splice donor site or initiation of translation codon.

Pathology and Pathogenesis

Induction of the rate-limiting hepatic enzyme ALAS1 is thought to underlie acute exacerbations of this and the other acute porphyrias. AIP remains latent (or asymptomatic) in the great majority of those who are heterozygous carriers of *PBGD* mutations, and this is almost always the case before puberty. In those with no history of acute symptoms, porphyrin precursor excretion is usually normal, suggesting that half-normal hepatic PBGD activity is sufficient unless hepatic ALAS1 activity is increased. Patients can also be asymptomatic with elevated levels of porphyrin precursors and are classified as *asymptomatic high excretors*. These patients may have a remote history of symptoms. Many factors that lead to clinical expression of AIP, including certain drugs and steroid hormones, have the capacity to induce hepatic ALAS1 and CYPs. When hepatic heme synthesis is increased, half-normal PBGD activity may become limiting, and ALA, PBG, and other heme pathway intermediates may accumulate. In addition, heme synthesis becomes impaired, and heme-mediated repression of hepatic ALAS1 is less effective.

It is not proved, however, that hepatic PBGD remains constant at approximately 50% of normal activity during exacerbations and remission of AIP, as in erythrocytes. An early report suggested that the enzyme activity is considerably less than half-normal in the liver during an acute attack. Hepatic PBGD activity might be reduced further once AIP becomes activated if, as suggested, excess PBG interferes with assembly of the dipyrromethane cofactor for this enzyme. It also seems likely that currently unknown genetic factors play a contributing role in, for example, patients who continue to have attacks even when known precipitants are avoided.

AIP is almost always latent before puberty and becomes active mostly in adult women, which suggests that endocrine factors, and especially adult levels of female steroid hormones, are important for clinical expression. Premenstrual attacks are probably the result of endogenous progesterone. Acute porphyrias are sometimes exacerbated by exogenous steroids, including oral contraceptive preparations containing progestins. Surprisingly, pregnancy is usually well tolerated, suggesting that beneficial metabolic changes may ameliorate the effects of high levels of progesterone.

Drugs that are unsafe in acute porphyrias (Table 110.3) include those having the capacity to induce hepatic ALAS1, which is closely associated with induction of CYPs. Some chemicals (e.g., griseofulvin) can increase heme turnover by promoting the destruction of specific CYPs to form an inhibitor (e.g., *N* -methyl protoporphyrin) of ferrochelatase (FECH, the final enzyme in the pathway). Sulfonamide antibiotics are harmful but apparently not inducers of hepatic heme synthesis. Ethanol and other alcohols are inducers of ALAS1 and some CYPs.

Table 110.3

Drugs Regarded as Unsafe and Safe in Acute Porphyrias

UNSAFE	**SAFE**
Barbiturates (all)	Narcotic analgesics
Sulfonamide antibiotics*	Aspirin
Meprobamate* (also mebutamate,* tybutamate*)	Acetaminophen (paracetamol)
Carisoprodol*	Phenothiazines
Glutethimide*	Penicillin and derivatives
Methyprylon	Streptomycin
Ethchlorvynol*	Glucocorticoids
Mephenytoin	Bromides
Phenytoin*	Insulin

Succinimides	Atropine
Carbamazepine[*]	Cimetidine
Clonazepam [‡]	Ranitidine [†]
Primidone[*]	Acetazolamide
Valproic acid[*]	Allopurinol
Pyrazolones (aminopyrine, antipyrine)	Amiloride
Griseofulvin[*]	Bethanidine
Ergots	Bumetanide
Metoclopramide[*] [‡]	Coumarins
Rifampin[*]	Fluoxetine
Pyrazinamide[*] [‡]	Gabapentin
Diclofenac[*] [‡]	Gentamicin
Fluconazole[*]	Guanethidine
Oral contraceptives	Ofloxacin
Progesterone and synthetic progestins[*]	Propranolol
Danazol[*]	Succinylcholine
Alcohol	Tetracycline
ACEIs (especially enalapril) [‡]	
Spironolactone	
CCBs (especially nifedipine) [‡]	
Ketoconazole	
Ketamine[*]	

[*] Porphyria has been listed as a contraindication, warning, precaution, or adverse effect in U.S. labeling for these drugs. Estrogens are also listed as harmful in porphyria but have been implicated as harmful in acute porphyrias, mostly based only on experience with estrogen-progestin combinations. Although estrogens can exacerbate porphyria cutanea tarda, there is little evidence they are harmful in the acute porphyrias.

[†] Porphyria has been listed as a precaution in U.S. labeling for this drug. However, this drug is regarded as safe by other sources.

[‡] These drugs have been classified as probably safe by some sources, but this is controversial, and they should be avoided.

This partial listing does not include all available information about drug safety in acute porphyrias. Other sources should be consulted for drugs not listed here.

ACEIs, Angiotensin-converting enzyme inhibitors; CCBs, calcium channel blockers.

Nutritional factors , principally reduced intake of calories and carbohydrates, as may occur with illness or attempts to lose weight, can increase porphyrin precursor excretion and induce attacks of porphyria. Increased carbohydrate intake may ameliorate attacks. Hepatic ALAS1 is modulated by the peroxisome proliferator-activated receptor-γ coactivator-1α, which is an important link between nutritional status and exacerbations of acute porphyria.

Other factors have been implicated. Chemicals in cigarette smoke, such as polycyclic aromatic hydrocarbons, can induce hepatic CYPs and heme synthesis.

A survey of AIP patients found an association between **smoking** and repeated porphyric attacks. Attacks may result from metabolic stress and impaired nutrition associated with major illness, infection, or surgery. Clinical observations suggest an additive effect of multiple predisposing factors, including drugs, endogenous hormones, nutritional factors, and smoking, are common.

Neurologic Mechanisms

The mechanism of neural damage in acute porphyrias is poorly understood. The most favored hypothesis at present is that 1 or more heme precursors, or perhaps a derivative, are neurotoxic. Increased ALA in AIP, HCP, VP, ADP, plumbism, and hereditary tyrosinemia type 1, which have similar neurologic manifestations, suggests that this substance or a derivative may be neuropathic. Porphyrins derived from ALA after its uptake into cells may have toxic potential. ALA can also interact with γ-aminobutyric acid (GABA) receptors. Severe AIP greatly improves after allogeneic liver transplantation. This experience and the demonstration that recipients of AIP livers develop porphyria support the hypothesis that heme precursors from the liver cause the neurologic manifestations.

Epidemiology

AIP occurs in all races and is the most common acute porphyria, with an estimated prevalence in most countries of 5 in 100,000. In Sweden, prevalence was estimated to be 7.7 in 100,000, including latent cases with normal porphyrin precursors. A much higher prevalence of 60-100 in 100,000 in northern Sweden is the result of a founder effect. The combined prevalence of AIP and VP in Finland is approximately 3.4 in 100,000. A survey of chronic psychiatric patients in the United States using an erythrocyte PBGD determination found a high prevalence (210 in 100,000) of PBGD deficiency, but a study in Mexico found a similar prevalence in psychiatric patients and controls. Population screening by erythrocyte PBGD activity or DNA analysis revealed a prevalence of 200 heterozygotes per 100,000 people in Finland, and 1 in approximately 1,675 (60 in 100,000) in France. Studies using exomic/genomic databases show that the estimated frequency of pathogenic mutations in the *HMBS* gene is 0.00056 (56 in 100,000) suggesting that the penetrance of this disorder may be as low as 1%, and that carriers of *PBGD* mutations that can cause AIP are much more common than previously believed.

Clinical Manifestations

Neurovisceral manifestations of acute porphyrias may appear any time after puberty, but rarely before (Table 110.4). Symptomatic childhood cases have been reported, but most were not adequately documented biochemically and confirmed by genetic testing. Abdominal pain is the most common presenting symptom in such cases, but seizures are common and may precede the diagnosis of AIP. Other manifestations reported in children include peripheral neuropathy, myalgias, hypertension, irritability, lethargy, and behavioral abnormalities. A population-based study in Sweden indicated that symptoms suggestive of porphyria may occur in heterozygotes during childhood, even, in contrast to adults, when urinary porphyria precursors are not elevated. This study did not compare the frequency of such nonspecific symptoms in a control group of children. Very rare cases of homozygous AIP present differently, with severe neurologic manifestations early in childhood.

Table 110.4

Common Presenting Symptoms and Signs of Acute Porphyria

SYMPTOMS AND SIGNS	FREQUENCY (%)	COMMENT
GASTROINTESTINAL		
Abdominal pain	85–95	Usually unremitting (for hours or longer) and poorly localized but can be cramping.
Vomiting	43–88	Neurologic in origin and rarely accompanied by peritoneal signs, fever, or leukocytosis.
Constipation	48–84	Nausea and vomiting often accompany abdominal pain. May be accompanied by bladder paresis.
Diarrhea	5–12	
NEUROLOGIC		
Pain in extremities, back	50–70	Pain may begin in the chest or back and move to the abdomen. Extremity pain chest, neck, or head indicates involvement of sensory nerves; objective sensory loss reported in 10–40% of cases.
Paresis	42–68	May occur early or late during a severe attack. Muscle weakness usually begins proximally rather than distally and more often in the upper than lower extremities.
Respiratory paralysis	9–20	Preceded by progressive peripheral motor neuropathy and paresis.
Mental	40–58	May range from minor behavioral changes to agitation, confusion,

symptoms		hallucinations, and depression.
Convulsions	10–20	A central neurologic manifestation of porphyria or caused by hyponatremia, which often results from syndrome of inappropriate antidiuretic hormone secretion or sodium depletion.
CARDIOVASCULAR		
Tachycardia	64–85	May warrant treatment to control rate, if symptomatic
Systemic arterial hypertension	36–55	May require treatment during acute attacks, and sometimes becomes chronic.

From Anderson KE, Bloomer JR, Bonkovsky HL, et al: Desnick recommendations for the diagnosis and treatment of the acute porphyrias, *Ann Intern Med* 142(6):439–450, 2005.

Acute attacks in adults are characterized by a constellation of nonspecific symptoms, which may become severe and life threatening. **Abdominal pain** occurs in 85–95% of AIP patients; is usually severe, steady, and poorly localized, but is sometimes cramping; and accompanied by signs of ileus, including abdominal distention and decreased bowel sounds. Nausea, vomiting, and constipation are common, but increased bowel sounds and diarrhea may occur. Bladder dysfunction may cause hesitancy and dysuria. **Tachycardia** , the most common physical sign, occurs in up to 80% of attacks. This is often accompanied by **hypertension** , restlessness, coarse or fine tremors, and excess sweating, which are attributed to sympathetic overactivity and increased catecholamines. Other common manifestations include mental symptoms; pain in the extremities, head, neck, or chest; muscle weakness; and sensory loss. Because all these manifestations are neurologic rather than inflammatory, there is little or no abdominal tenderness, fever, or leukocytosis.

Porphyric neuropathy is primarily motor and appears to result from axonal degeneration rather than demyelinization. Sensory involvement is indicated by pain in the extremities, which may be described as muscle or bone pain, and by numbness, paresthesias, and dysesthesias. Paresis may occur early in an attack but is more often a late manifestation in an attack that is not recognized and adequately treated. Rarely, severe neuropathy develops when there is little or no abdominal pain. Motor weakness most commonly begins in the proximal muscles of the upper extremities and then progresses to the lower extremities and the periphery. It is usually symmetric, but occasionally asymmetric or focal. Initially, tendon reflexes may be little affected or hyperactive and become decreased or absent. Cranial nerves, most often X and VII, may be affected, and blindness from involvement of the optic nerves or occipital lobes has been reported. More common central nervous system (CNS) manifestations include seizures, anxiety, insomnia, depression, disorientation, hallucinations, and paranoia. Seizures may result from hyponatremia, porphyria itself, or an unrelated cause. Chronic depression and other mental symptoms occur in some patients, but attribution to porphyria is often difficult.

Hyponatremia is common during acute attacks. Inappropriate antidiuretic hormone (ADH) secretion is often the most likely mechanism, but salt depletion from excess renal sodium loss, gastrointestinal (GI) loss, and poor intake have been suggested as causes of hyponatremia in some patients. Unexplained reductions in total blood and red blood cell volumes are sometimes found and increased ADH secretion might then be an appropriate physiologic response. Other electrolyte abnormalities may include hypomagnesemia and hypercalcemia.

The attack usually resolves within several days, unless treatment is delayed. Abdominal pain may resolve within a few hours and paresis within a few days. Even severe motor neuropathy can improve over months or several years, but may leave some residual weakness. Progression of neuropathy to respiratory paralysis and death seldom occurs with appropriate treatment and removal of harmful drugs. Sudden death may result from cardiac arrhythmia.

Laboratory Findings

Levels of ALA and PBG are substantially increased during acute attacks. These levels may decrease after an attack but usually remain increased unless the disease becomes asymptomatic for a prolonged period.

Porphyrins are also markedly increased, which accounts for reddish urine in AIP. These are predominantly uroporphyrins, which can form nonenzymatically from PBG. Because the increased urinary porphyrins in AIP are predominantly isomer III, however, their formation is likely to be largely enzymatic, which might occur if excess ALA produced in the liver enters cells in other tissues and is then converted to porphyrins by the heme biosynthetic pathway. Porphobilin, a degradation product of PBG, and dipyrrylmethenes appear to account for brownish urinary discoloration. Total fecal porphyrins and plasma porphyrins are normal or slightly increased in AIP. Erythrocyte protoporphyrin may be somewhat increased in patients with manifest AIP.

Erythrocyte PBGD activity is approximately half-normal in most patients with AIP. The normal range is wide and overlaps with the range for AIP heterozygotes. Some *PBGD* gene mutations cause the enzyme to be deficient only in nonerythroid tissues. PBGD activity is also highly dependent on erythrocyte age, and an increase in erythropoiesis from concurrent illness in an

AIP patient may raise the activity into the normal range. Thus, PBGD activity alone is insufficient to make the diagnosis of AIP.

Diagnosis and Differential Diagnosis

An increased urinary PBG level establishes that a patient has 1 of the 3 most common acute porphyrias (see Table 110.2). Measuring PBG in serum is preferred when there is coexistent severe renal disease but is less sensitive when renal function is normal. Measurement of urinary ALA is less sensitive than PBG and also less specific, but will detect ADP, the 4th type of acute porphyria. Erythrocyte PBGD activity is decreased in most AIP patients and helps confirm the diagnosis in a patient with high PBG. A normal enzyme activity in erythrocytes does not exclude AIP.

Knowledge of the *PBGD* mutation in a family enables reliable identification of other gene carriers. Prenatal diagnosis can be performed by amniocentesis or chorionic villus sampling (CVP) in a fetus with a known *PBGD* mutation in the family. Prenatal diagnosis is typically not performed due to the low penetrance of the disorder and favorable prognosis with treatment.

Complications

AIP and other acute porphyrias are typically associated with mild abnormalities in liver function tests; some patients develop chronic liver disease. The risk of hepatocellular carcinoma is also increased, perhaps 60-70–fold after age 50, even in asymptomatic individuals who have increased porphyrins or porphyrin precursors. Few patients who developed this neoplasm had increases in serum α-fetoprotein. Patients with acute porphyrias, especially >50 yr old, should be screened at least yearly by ultrasound or an alternative imaging method.

The risk of chronic hypertension and impaired renal function is increased in these patients, most often with evidence of interstitial nephritis. A nephrotoxic effect of ALA may contribute. This may progress to severe renal failure and require renal transplantation.

Patients with recurrent attacks may develop **chronic neuropathic pain** , although this has not been well characterized. Referral to a neurologist is recommended for any patient with ongoing or residual neurologic symptoms. In addition, depression and anxiety are common in these patients.

Treatment

Hemin

Intravenous (IV) hemin is the treatment of choice for most *acute* attacks of porphyria. There is a favorable biochemical and clinical response to early treatment with hemin, but less rapid clinical improvement if treatment is delayed. It is no longer recommended that therapy with hemin for a severe attack be started only after an unsuccessful trial of IV glucose for several days. Mild attacks without severe manifestations, such as paresis, seizures, hyponatremia, or pain requiring opioids, may be treated with IV glucose. After IV administration, hemin binds to hemopexin and albumin in plasma and is taken up primarily in hepatocytes, where it augments the regulatory heme pool in hepatocytes, represses the synthesis of hepatic ALAS1, and dramatically reduces porphyrin precursor overproduction.

Hemin* is available for IV administration in the United States as *lyophilized hematin* (Panhematin, Recordati). Degradation products begin to form as soon as the lyophilized product is reconstituted with sterile water, and these are responsible for phlebitis at the site of infusion and a transient anticoagulant effect. Loss of venous access due to phlebitis is common after repeated administration. Stabilization of lyophilized hematin by reconstitution with 30% human albumin can prevent these adverse effects; this is recommended especially if a peripheral vein is used for the infusion. Uncommon side effects of hemin include fever, aching, malaise, hemolysis, anaphylaxis, and circulatory collapse. Heme arginate, a more stable hemin preparation, is available in Europe and South Africa.

Hemin treatment should be instituted only after a diagnosis of acute porphyria has been initially confirmed by a marked increase in urinary PBG. When prior documentation of the diagnosis is available for review, it is not essential to confirm an increase in PBG with every recurrent attack, if other causes of the symptoms are excluded clinically. The standard regimen of hemin for treatment of acute porphyric attacks is 3-4 mg/kg/day for 4 days. Lower doses have less effect on porphyrin precursor excretion and probably less clinical benefit.

General and Supportive Measures

Drugs that may exacerbate porphyrias (see Table 110.3) should be discontinued whenever possible, and other precipitating factors identified. Hospitalization is warranted, except for mild attacks; for treatment of severe pain, nausea, and vomiting; for administration of hemin and fluids; and for monitoring vital capacity, nutritional status, neurologic function, and electrolytes. Pain usually requires an opioid; there is low risk for addiction after recovery from the acute attack. Ondansetron or a phenothiazine such as chlorpromazine is needed for nausea, vomiting, anxiety, and restlessness. Low doses of short-acting benzodiazepines can be given for restlessness or insomnia. β-Adrenergic blocking agents may be useful during acute attacks to control tachycardia and hypertension but may be hazardous in patients with hypovolemia and incipient cardiac failure.

Carbohydrate Loading

The effects of carbohydrates on repressing hepatic ALAS1 and reducing porphyrin precursor excretion are weak compared to those of hemin. Therefore, carbohydrate loading is seldom beneficial except in mild attacks. Glucose polymer solutions by mouth are sometimes tolerated. At least 300 g of IV glucose, usually given as a 10% solution, has been recommended for adults hospitalized with attacks of porphyria. Amounts up to 500 g daily may be more effective, but large volumes may favor development of hyponatremia.

Other Therapies

Liver transplantation was effective in several patients with severe AIP. A group from the United Kingdom reported their experience with liver transplantation in 10 AIP patients with significantly impaired quality of life and recurrent attacks refractory to medical management. Patients had a complete biochemical and symptomatic resolution after transplantation; 2 patients succumbed to multiorgan failure. Liver transplantation was also successful in a U.S. patient with AIP and intractable symptoms who became unresponsive to hemin therapy; liver transplantation normalized porphyrin precursor excretion, and symptoms resolved. However, liver transplantation is a high-risk procedure and should be considered only as a last resort. Hepatocyte-targeted RNA interference (**RNAi**) therapy is being developed to reverse directly the extremely elevated hepatic ALAS1 mRNA in this disease. Preliminary results from clinical trials are promising.

Seizures and Other Complications

Seizures caused by hyponatremia or other electrolyte imbalances may not require prolonged treatment with anticonvulsant drugs, most of which have at least some potential for exacerbating acute porphyrias. Bromides, gabapentin, and probably vigabatrin are safe. Clonazepam may be less harmful than phenytoin or barbiturates. Control of hypertension is important and may help prevent chronic renal impairment, which can progress and require renal transplantation.

Safe and Unsafe Drugs

Patients often do well with avoidance of harmful drugs. Table 110.3 lists some drugs known or strongly suspected to be harmful or safe in the acute porphyrias. More extensive listings are available from the **European Porphyria Network** (www.porphyria-europe.com) and **American Porphyria Foundation** (www.porphyriafoundation.com), but some listings are controversial. Information regarding safety is lacking for many drugs, especially for those recently introduced.

Exogenous progestins, usually in combination with estrogens, can induce attacks of porphyria. Estrogens are seldom reported to be harmful when given alone. Synthetic steroids with an ethynyl substituent can cause a mechanism-based destruction of hepatic CYPs and should probably be avoided in patients with acute porphyria. Danazol is especially contraindicated.

Other Situations

Major surgery can be carried out safely in patients with acute porphyria, especially if barbiturates are avoided. Halothane has been recommended as an inhalation agent and propofol and midazolam as IV induction agents.

Pregnancy is usually well tolerated, which is surprising, because levels of progesterone, a potent inducer of hepatic ALAS1, are considerably increased during pregnancy. Some women do experience continuing attacks during pregnancy. This has sometimes been attributed to reduced caloric intake or metoclopramide, a drug sometimes used to treat hyperemesis gravidarum and considered harmful in acute porphyrias.

Diabetes mellitus and other endocrine conditions are not known to precipitate attacks of porphyria. In fact, the onset of diabetes mellitus and resulting high circulating glucose levels may decrease the frequency of attacks and lower porphyrin precursor levels in AIP.

Prognosis

The outlook for patients with acute porphyrias has improved greatly in the past several decades. In Finland, for example, 74% of patients with AIP or VP reported that they led normal lives, and <30% had recurrent attacks during several years of follow-up. In those presenting with acute symptoms, recurrent attacks were most likely within the next 1-3 yr. Moreover, only 6% of gene carriers who had never had attacks developed symptoms. The improved outlook may result from earlier detection, better treatment of acute attacks, and replacement of harmful drugs such as barbiturates and sulfonamides with safer drugs. However, some patients continue to have recurrent attacks, chronic pain, and other symptoms, even after avoiding known exacerbating factors.

Prevention

For prevention of attacks, it is important to identify multiple inciting factors and remove as many as possible. Drugs for concurrent medical conditions should be reviewed. Because dietary factors are often unapparent, consultation with a dietitian may be useful. A well-balanced diet that is somewhat high in carbohydrate (60–70% of total calories) and sufficient to maintain weight is recommended. There is little evidence that additional dietary carbohydrate helps further in preventing attacks, and it may lead to weight gain. Patients who wish to lose excess weight should do so gradually and when they are clinically stable. Rapid weight loss after bariatric surgery may exacerbate acute porphyrias. Iron deficiency, which can be detected by a low serum ferritin level, should be corrected.

Gonadotropin-releasing hormone (GnRH) analogs, which reversibly suppress ovulation, can be dramatically effective for preventing frequently recurring luteal phase attacks, but baseline and continuing gynecologic evaluation and bone mineral density measurements are important; transdermal estrogen or a bisphosphonate may be added to prevent bone loss. Hemin administered once or twice weekly can prevent frequent, noncyclic attacks of porphyria in some patients. Alternatively, single-dose hemin can be administered “on demand” at an outpatient infusion center to abort an attack and prevent hospitalization, if a patient can recognize early “prodromal” symptoms. Inpatient management is warranted, however, if advanced manifestations such as vomiting, paresis, or other neuropsychiatric symptoms have developed.

Genetic Counseling

A mutation identified in the index case can be sought in the child. Counseling should emphasize that the great majority of those who inherit a *PBGD* mutation never develop symptoms, and the prognosis of those who do is favorable. Therefore a normal, healthy life is expected, especially with avoidance of harmful drugs and other factors and prompt recognition and treatment of symptoms should they occur. Given the favorable outlook for most mutation carriers, even during pregnancy, having children is not precluded, and prenatal diagnosis of acute porphyrias is less important than it is for many other inherited diseases.

Congenital Erythropoietic Porphyria

Also termed *Günther disease*, this rare disease usually presents with photosensitivity shortly after birth or in utero as nonimmune hydrops.

Etiology

CEP is an autosomal recessive disease caused by a marked deficiency of uroporphyrinogen III synthase (UROS). Many *UROS* mutations have been identified among CEP families. Later-onset disease in adults is likely to be associated with myeloproliferative disorders and expansion of a clone of erythroblasts that carry a *UROS* mutation.

Pathology and Pathogenesis

UROS, which is extremely deficient in CEP, catalyzes inversion of pyrrole ring D of HMB and rapid cyclization of the linear tetrapyrrole to form uroporphyrinogen III. This enzyme is also termed *uroporphyrinogen III cosynthase*. The human enzyme is a monomer. The gene for the enzyme is found on chromosome 10q25.3→q26.3 and contains 10 exons. Erythroid and housekeeping transcripts are generated by alternative promoters but encode the same enzyme.

In CEP, HMB accumulates in erythroid cells during hemoglobin synthesis and cyclizes nonenzymatically to form uroporphyrinogen I, which is auto-oxidized to uroporphyrin I. Some of the uroporphyrinogen I that accumulates is metabolized to coproporphyrinogen I, which accumulates because it is not a substrate for coproporphyrinogen oxidase. Thus, both uroporphyrin I and coproporphyrin I accumulate in the bone marrow and are then found in circulating erythrocytes, plasma, urine, and feces.

A variety of *UROS* mutations have been identified in CEP, including missense and nonsense mutations, large and small deletions and insertions, splicing defects, and intronic branch point mutations. At least 4 mutations have been identified in the erythroid-specific promoter. Many patients inherited a different mutation from each parent, and most mutations have been detected in only one or a few families. An exception is a common mutation, C73R, which is at a mutational hot spot and was found in approximately 33% of alleles. One child with CEP had a *GATA1* mutation, with no *URO* S mutation. The CEP phenotype may be modulated by gain of function *ALAS2* mutations, which were first identified as causing XLP.

Genotype–phenotype correlations have been based on the in vitro expression of various CEP mutations and the severity of associated phenotypic manifestations. The C73R allele, which is associated with a severe phenotype in homozygotes or in patients heteroallelic for C73R and another mutation expressing little residual activity, resulted in <1% of normal enzyme activity. Patients with the C73R allele and heteroallelic for other mutations expressing more residual activity have milder disease.

Hemolysis is a common feature of CEP. Excess porphyrins in circulating erythrocytes cause cell damage, perhaps by a phototoxic mechanism, leading to both intravascular hemolysis and increased splenic clearance of erythrocytes. Also important is ineffective erythropoiesis, with intramedullary destruction of porphyrin-laden erythroid cells and breakdown of heme. Expansion of the bone marrow as a result of erythroid hyperplasia may contribute, along with vitamin D deficiency, to bone loss. Nutrient deficiencies sometimes cause erythroid hypoplasia. Despite the marked deficiency of UROS, heme production in the bone marrow is increased because of hemolysis and a compensatory increase in hemoglobin production. This occurs, however, at the expense of marked accumulation of HMB, which is converted to porphyrinogens and porphyrins.

Clinical Manifestations

In severe cases, CEP can cause fetal loss or may be recognized in utero as causing intrauterine hemolytic anemia and **nonimmune hydrops fetalis** . CEP may be associated with neonatal hyperbilirubinemia, and *phototherapy may unintentionally induce severe photosensitivity and scarring.*

The most characteristic presentation is reddish urine or pink staining of diapers by urine or meconium shortly after birth (Fig. 110.2). With sun exposure, severe blistering lesions appear on exposed areas of skin on the face and hands and have been termed *hydroa estivale* because they are more severe with greater sunlight exposure during summer (Fig. 110.3). Vesicles and bullae, as well as friability, hypertrichosis, scarring, thickening, and areas of hypopigmentation and hyperpigmentation are very similar to those seen in PCT but usually much more severe. Infection and scarring sometimes cause loss of facial features and fingers and damage to the cornea, ears, and nails. Porphyrins are deposited in dentin and bone in utero. Reddish brown teeth in normal light, an appearance termed **erythrodontia** , display reddish fluorescence under long-wave UV light (Fig. 110.4). Unaffected children born to a mother with CEP may have erythrodontia. Hemolysis and splenomegaly are common in CEP. Bone marrow compensation may be adequate, especially in milder cases. Patients with severe phenotypes, however, are often transfusion dependent. Splenomegaly may contribute to the anemia and cause leukopenia and thrombocytopenia, which may be complicated by significant bleeding. Neuropathic symptoms are absent, and there is no sensitivity to drugs, hormones, or carbohydrate restriction. The liver may be damaged by iron overload or viral hepatitis acquired from blood transfusions.

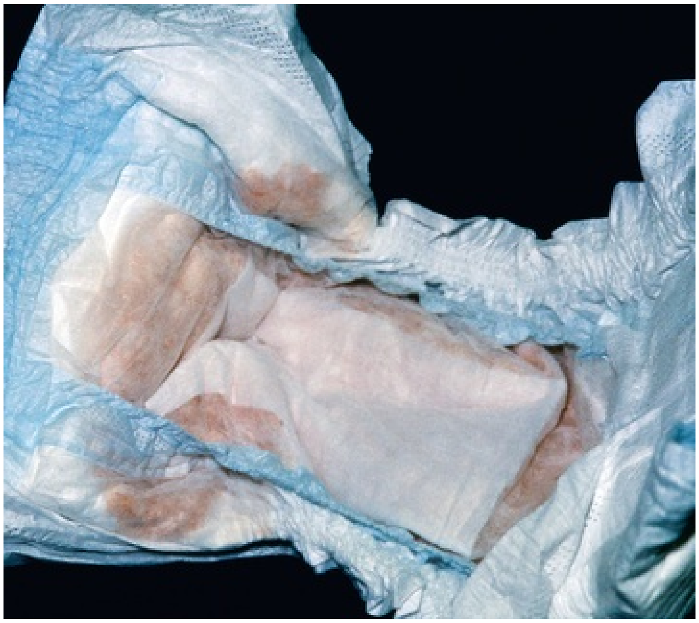

FIG. 110.2 Congenital erythropoietic porphyria (CEP). The diaper of a baby with CEP demonstrates the red color of urine. (From Paller AS, Macini AJ: *Hurwitz clinical pediatric dermatology* , ed 3, Philadelphia, 2006, Elsevier Saunders, p 517.)

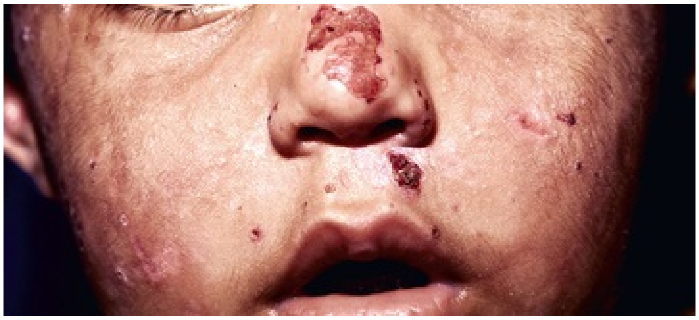

FIG. 110.3 Congenital erythropoietic porphyria. Vesicles, bullae, and crusts on sun-exposed areas. (From Paller AS, Macini AJ: *Hurwitz clinical pediatric dermatology* , ed 3, Philadelphia, 2006, Elsevier Saunders, p 517.)

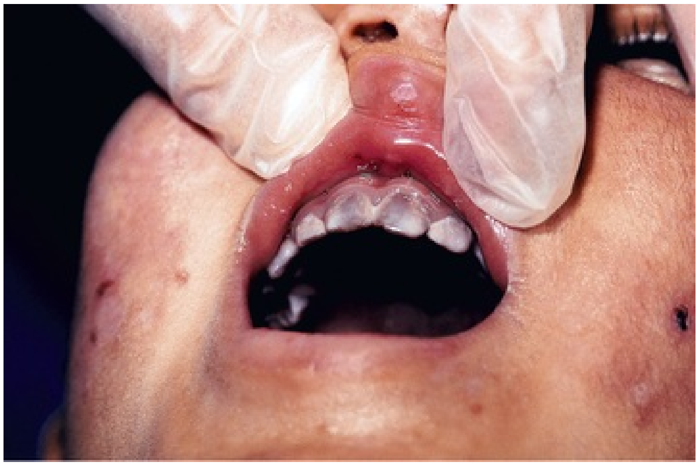

FIG. 110.4 Congenital erythropoietic porphyria. Brownish teeth that fluoresce under Wood lamp examination. (From Paller AS, Macini AJ: *Hurwitz clinical pediatric dermatology* , ed 3, Philadelphia, 2006, Elsevier Saunders, p 517.)

Milder cases of CEP with onset of symptoms in adult life and without erythrodontia may mimic PCT. These late-onset cases are likely to be associated with myeloproliferative disorders and expansion of a clone of cells carrying a *UROS* mutation.

Laboratory Findings

Urinary porphyrin excretion and circulating porphyrin levels in CEP are much higher than in almost all other porphyrias. Urinary porphyrin excretion can be as high as 50-100 mg daily and consists mostly of uroporphyrin I and coproporphyrin I. ALA and PBG are normal. Fecal porphyrins are greatly increased, with a predominance of coproporphyrin I.

Marked increases in erythrocyte porphyrins in CEP also consist mostly of uroporphyrin I and coproporphyrin I. These porphyrins are also increased in bone marrow, spleen, plasma, and to a lesser extent, liver. The porphyrin pattern in erythrocytes is influenced by rates of erythropoiesis and erythroid maturation. A predominance of protoporphyrin has been noted in some CEP patients, and in 1 such patient, uroporphyrin and coproporphyrin increased when erythropoiesis was stimulated by blood removal.

Diagnosis and Differential Diagnosis

The diagnosis of CEP should be documented by full characterization of porphyrin patterns and identification of the underlying mutations. In later-onset cases, an underlying myeloproliferative disorder and a *UROS* somatic mutation should be suspected and studied in detail.

The clinical picture in hepatoerythropoietic porphyria (HEP) may be very similar, but the porphyrin patterns in urine and feces in HEP resemble PCT. A predominant increase in erythrocyte protoporphyrin is unusual in CEP but is characteristic of HEP as well as rare homozygous cases of AIP, HCP, and VP. EPP and XLP are also distinguished by normal urinary porphyrins and by increases in erythrocyte metal-free protoporphyrin, whereas the increased protoporphyrin in other conditions is mostly complexed with zinc.

CEP should be suspected as a cause of nonimmune hydrops or hemolytic anemia in utero. With recognition of the disease at this stage, intrauterine transfusion can be considered, avoiding severe, scarring photosensitivity from phototherapy for hyperbilirubinemia after birth. Prenatal diagnosis is feasible by finding red-brown discoloration and increased porphyrins in amniotic fluid and measuring porphyrins in fetal erythrocytes and plasma. UROS activity can be measured in cultured amniotic fluid cells, or *UROS* mutations identified in chorionic villi or cultured amniotic cells.

Treatment

Protection from sunlight exposure, minimizing skin trauma, and prompt treatment of any cutaneous infections are essential in managing CEP. Sunscreen lotions and beta-carotene are sometimes beneficial. Transfusions to achieve a level of hemoglobin sufficient to suppress erythropoiesis significantly can be quite effective in reducing porphyrin levels and photosensitivity. Concurrent deferoxamine to reduce iron overload and hydroxyurea to suppress erythropoiesis further may provide additional benefit. Splenectomy reduces hemolysis and transfusion requirements in some patients. Oral charcoal may increase fecal loss of porphyrins but may contribute little in more severe cases. IV hemin may be somewhat effective but has not been extensively studied and seems unlikely to provide long-term benefit.

The most effective treatment is marrow stem cell transplantation in early childhood, which has greatly reduced porphyrin levels and photosensitivity and increased long-term survival.

Prognosis

The outlook is favorable in milder cases and in patients with more severe disease, especially after successful bone marrow or stem cell transplantation. Otherwise, prognosis relates to adherence to sunlight avoidance.

Prevention and Genetic Counseling

Genetic counseling is important for affected families because CEP can be recognized before birth, and a severe phenotype can often be predicted by identifying the nature of the *UROS* mutations.

Porphyria Cutanea Tarda

Porphyria cutanea tarda is the most common and readily treated human porphyria (see Table 110.2). It occurs in mid or late adult life and is rare in children. Previous terms include *symptomatic porphyria, PCT symptomatica,* and *idiosyncratic porphyria.* The underlying cause is a liver-specific, acquired deficiency of uroporphyrinogen decarboxylase (UROD) with contributions by several types of genetic and acquired susceptibility factors, including heterozygous *UROD* mutations in familial PCT. HEP, the homozygous form of familial PCT, usually has a more severe presentation in childhood, resembling CEP clinically.

Etiology

PCT is caused by a reduction of hepatic UROD activity to ≤20% of normal activity. An inhibitor of hepatic UROD has been characterized as a *uroporphomethene* , which is derived from partial oxidation of the enzyme substrate uroporphyrinogen. CYPs, such as CYP1A2, as well as iron, are involved in its formation (Fig. 110.5). Although enzyme activity is inhibited, the amount of hepatic enzyme protein measured immunochemically remains at its genetically determined level.

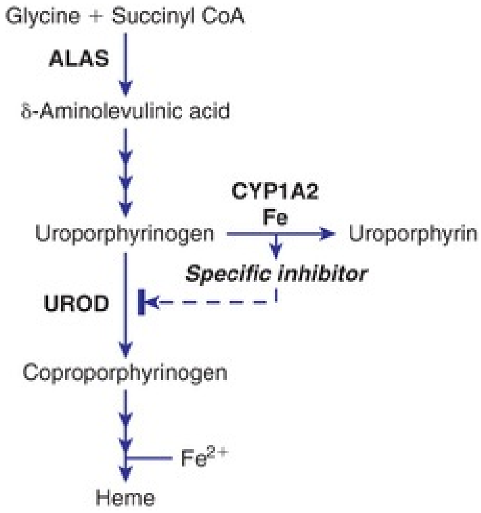

FIG. 110.5 Formation of a specific inhibitor of uroporphyrinogen decarboxylase in the liver in porphyria cutanea tarda. ALAS, δ-Aminolevulinic acid synthase; CYP1A2, cytochrome P450 1A2; UROD, uroporphyrinogen decarboxylase.

UROD catalyzes the decarboxylation of the 4 acetic acid side chains of uroporphyrinogen (an octacarboxyl porphyrinogen) to form coproporphyrinogen (a tetracarboxyl porphyrinogen). The enzyme reaction occurs in a sequential, clockwise fashion, with the intermediate formation of hepta-, hexa-, and pentacarboxyl porphyrinogens. Uroporphyrinogen III, as compared with other uroporphyrinogen isomers, is the preferred substrate. Human UROD is a dimer with the 2 active site clefts juxtaposed. The UROD gene is on chromosome 1p34 and contains 10 exons, with only 1 promoter. Therefore the gene is transcribed as a single mRNA in all tissues.

The majority of PCT patients (80%) have no *UROD* mutations and have sporadic (**type 1**) disease. Some are heterozygous for *UROD* mutations and have familial (**type 2**) PCT. Described mutations include missense, nonsense, and splice-site mutations; several small and large deletions; and small insertions, with only a few identified in more than 1 family. A few of these mutations may be located near the active site cleft, but most appear to involve regions with important structural roles. Being heterozygous for a *UROD* mutation is insufficient to cause PCT. Individuals with type 2 PCT are born with 50% of normal UROD activity, and later in life other susceptibility factors (as in type 1) lead to production of the uroporphomethene inhibitor and further reduction on hepatic UROD activity to <20% of normal. Because penetrance of the genetic trait is low, many patients with familial PCT have no family history of the disease.

Induction of hepatic ALAS1 is not a prominent feature in PCT, although alcohol may increase this enzyme slightly. Iron and estrogens are not potent inducers of ALAS1, and drugs that are potent inducers of ALAS1 and CYPs are much less frequently implicated in PCT than in acute porphyrias.

Blistering skin lesions result from porphyrins that are released from the liver. Sunlight exposure leads to generation of reactive oxygen species (ROS) in the skin, complement activation, and lysosomal damage.

Epidemiology

Differences in prevalence probably relate to geographic variations in susceptibility factors such as hepatitis C and ethanol use. The yearly incidence in the United Kingdom was estimated at 2-5 in 1 million in the general population, and the prevalence in the United States and Czechoslovakia was estimated at 1 in 25,000 and 1 in 5,000 in the general population, respectively. The disease was reported to be prevalent in the Bantus of South Africa in association with iron overload. PCT is more common in males, possibly because of greater alcohol intake, and in women it is usually associated with estrogen use.

A massive outbreak of PCT occurred in eastern Turkey in the 1950s. Wheat intended for planting and treated with hexachlorobenzene as a fungicide was consumed by many at a time of food shortage. Cases and small outbreaks of PCT after exposure to other chemicals including di- and trichlorophenols and 2,3,7,8-tetrachlorodibenzo-*p* -dioxin (TCDD, dioxin) have been reported. The manifestations improved in most cases when the exposure was stopped. There are reported cases of delayed onset many years after chemical exposure.

Pathology and Pathogenesis

Porphyria cutanea tarda is classified into 3 clinically similar types. Generation of a UROD inhibitor in the liver plays an important role in all 3 types. The 80% of patients with type 1 (**sporadic**) PCT have no *UROD* mutations, and UROD activity is normal in nonhepatic tissues such as erythrocytes. In type 2 (**familial**) PCT, a heterozygous *UROD* mutation results in a partial (approximately 50%) deficiency of UROD in all tissues from birth, and the disease becomes active in some heterozygotes after further reduction of hepatic UROD activity to ≤20% of normal. HEP results from inheritance of a *UROD* mutation from each parent and typically causes severe photosensitivity resembling CEP starting in early childhood. Some compound heterozygotes have developed symptoms in childhood more typical of PCT. **Type 3** is rare and describes PCT without a *UROD* mutation occurring in more than 1 family member. Another genetic basis, such as *HFE* mutations, may be identified in type 3.

CYPs, especially CYP1A2, can catalyze the oxidation of uroporphyrinogen to uroporphyrin. This uroporphyrinogen oxidase activity is enhanced by iron and leads to formation of a UROD inhibitor (see Fig. 110.5). CYP1a2 seems essential for development of uroporphyria in rodents, because experimental uroporphyria does not develop in *CYP1a2* knockout mice.

Susceptibility Factors

The following factors are implicated in the development of PCT, and these occur in various combinations in individual patients.

Iron

A normal or increased amount of iron in the liver is essential for developing PCT, and treatment by phlebotomy to reduce hepatic iron leads to remission. Serum ferritin levels are usually in the upper part of the normal range or moderately increased, and liver histology commonly shows increased iron staining. Prevalence of the C282Y mutation of the *HFE* gene, which is the major cause of hemochromatosis in people of northern European ancestry, is increased in both type 1 and type 2 PCT, and approximately 10% of patients are C282Y homozygotes. In southern Europe the H63D mutation is more prevalent. PCT may develop in patients with secondary iron overload. Reduced hepatic expression of the hormone hepcidin occurs in hemochromatosis and also in PCT, regardless of *HFE* genotype, which may explain hepatic siderosis in this condition.

Hepatitis C

Hepatitis C virus (HCV) infection is highly prevalent in PCT in most geographic locations; in the United States, for example, HCV is present in 56–74% of cases, which is similar to rates in southern Europe. Prevalence of hepatitis C in PCT is lower in northern Europe (<20%). Steatosis and oxidative stress in HCV infection may favor iron-mediated generation of ROS and a UROD inhibitor. Dysregulation of hepcidin occurs in hepatitis C and may lead to increased iron absorption.

Human Immunodeficiency Virus

Many reports suggest that HIV infection can contribute to the development of PCT, although less frequently than HCV.

Ethanol

The long-recognized association between alcohol and PCT may be explained by the generation of ROS, which may cause oxidative damage, mitochondrial injury, depletion of reduced glutathione and other antioxidant defenses, increased production of endotoxin, and activation of Kupffer cells. Also, alcohol may contribute to iron overload by impairing hepcidin production.

Smoking and Cytochrome P450 Enzymes

Smoking has not been extensively studied as a susceptibility factor but is often associated with alcohol use in PCT. It may act to induce hepatic CYPs and oxidative stress. Hepatic CYPs are thought to be important in oxidizing uroporphyrinogen and generating a UROD inhibitor (see Fig. 110.5). Genetic polymorphisms of *CYP1A2* and *CYP1A1* have been implicated in human PCT. The frequency of an inducible *CYP1A2* genotype was more common in PCT patients than in controls in several studies.

Antioxidant Status

Ascorbic acid deficiency contributes to uroporphyria in laboratory models and perhaps in human PCT. In one series, plasma ascorbate levels were substantially reduced in 84% of patients with PCT. Low levels of serum carotenoids were also described, further suggesting that oxidant stress in hepatocytes is important in PCT.

Estrogens

Use of estrogen-containing oral contraceptives (OCs) or postmenopausal estrogen replacement therapy is frequently associated with PCT (type 1 or 2) in women. PCT sometimes occurs during pregnancy, although it is not clear whether the risk is increased.

Clinical Manifestations

Cutaneous Manifestations

PCT is readily recognized by blistering and crusted skin lesions on the backs of the hands, which are the most sun-exposed areas of the body, and somewhat less often on the forearms, face, ears, neck, legs, and feet (Fig. 110.6). The fluid-filled vesicles usually rupture and become crusted or denuded areas, heal slowly, and are subject to infection. The skin on the backs of the hands is characteristically friable, and minor trauma may cause blisters or denudation of skin. Small white plaques, termed *milia,* may precede or follow vesicle formation. Facial hypertrichosis and hyperpigmentation are also common. Severe scarring and thickening of sun-exposed skin may resemble scleroderma. Skin biopsy findings include subepidermal blistering and deposition of periodic acid–Schiff-(PAS)–positive material around blood vessels and fine fibrillar material at the dermoepithelial junction, which may be related to excessive skin fragility. IgG, other immunoglobulins, and complement are also deposited at the dermoepithelial junction and around dermal blood vessels. The skin lesions and histologic changes are not specific for PCT. The same findings occur in VP and HCP and resemble those of CEP and HEP, but are usually less severe. PCT usually develops in mid or late adult life. Onset in early adult life may be seen in those with *UROD* or *HFE* mutations. Childhood onset is rare and may be associated with cancer chemotherapy and *UROD* mutations.

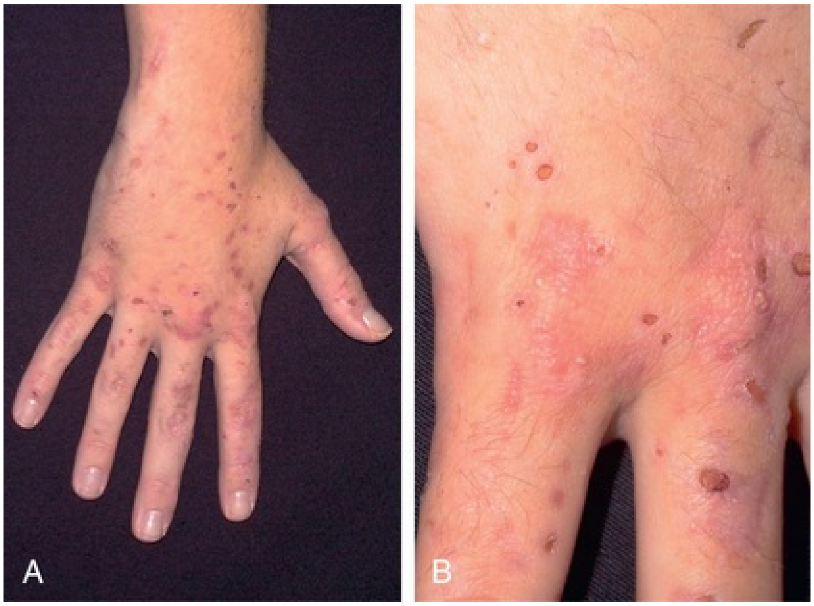

FIG. 110.6 **Porphyria cutanea tarda (PCT). A, Right hand of a patient with PCT, revealing numerous erosions and erythematous patches. B, Close-up of right hand. (From Horner**

ME, Alikhan A, Tintle S, et al: Cutaneous porphyrias. Part 1. Epidemiology, pathogenesis, presentation, diagnosis, and histopathology, *Int J Dermatol* 52:1464–1480, 2013, Fig 2, p 1470.)

Liver Abnormalities

PCT is almost always associated with nonspecific liver abnormalities, especially increased serum transaminases and γ-glutamyltranspeptidase, even in the absence of heavy alcohol intake or hepatitis C. Most histologic findings, such as necrosis, inflammation, increased iron, and increased fat, are nonspecific. Specific findings include red fluorescence of liver tissue, and fluorescent, birefringent, needle-like inclusions presumably consisting of porphyrins. Electron microscopy shows these inclusions are in lysosomes, and paracrystalline inclusions are found in mitochondria. Distorted lobular architecture and cirrhosis are more common with long-standing disease.

The risk of developing hepatocellular carcinoma is increased, with reported incidences ranging from 4–47% in PCT. These tumors seldom contain large amounts of porphyrins.

Other Features and Associations

Mild or moderate erythrocytosis in some adult patients is not well understood, but chronic lung disease from smoking may contribute. An earlier onset of symptoms may be noted in patients with genetic predisposing factors, such as an inherited partial deficiency of UROD or the C282Y/C282Y *HFE* genotype. Iron overload secondary to conditions such as myelofibrosis and end-stage renal disease (ESRD) may be associated with PCT. The disease can be especially severe in patients with ESRD because the lack of urinary excretion leads to much higher concentrations of porphyrins in plasma, and the excess porphyrins are poorly dialyzable. PCT occurs more frequently in patients with systemic lupus erythematosus and other immunologic disorders than would be expected by chance.

Laboratory Findings

Porphyrins accumulate in the liver mostly as the oxidized porphyrins rather than porphyrinogens in PCT, as indicated by the immediate *red fluorescence* observed in liver tissue. This develops over weeks or months before porphyrins appear in plasma and are transported to the skin, causing photosensitivity. In contrast to the acute hepatic porphyrias, only a very small increase in synthesis of heme pathway intermediates and little or no increase in hepatic ALAS1 are required to account for the excess porphyrins excreted in PCT.

Hepatic UROD deficiency leads to a complex pattern of excess porphyrins, which initially accumulate as porphyrinogens and then undergo nonenzymatic oxidation to the corresponding porphyrins (uro-, hepta-, hexa-, and pentacarboxyl porphyrins, and isocoproporphyrins). Uroporphyrin and heptacarboxyl porphyrin predominate in urine, with lesser amounts of coproporphyrin and penta- and hexacarboxyl porphyrin. A normally minor pathway is accentuated by UROD deficiency, whereby pentacarboxyl porphyrinogen is oxidized by coproporphyrinogen oxidase (CPOX; the next enzyme in the pathway), forming isocoproporphyrinogen, an atypical tetracarboxyl porphyrinogen. Relative to normal values, urinary porphyrins are increased to a greater extent than fecal porphyrins. However, the total amount of porphyrins excreted in feces in PCT exceeds that in urine, and total excretion of type III isomers (including isocoproporphyrins, which are mostly derived from the type III series) exceeds that of type I isomers. Perhaps because uroporphyrinogen III is the preferred substrate for UROD, more uroporphyrinogen I than III accumulates and is excreted as uroporphyrin I in PCT. Hepta- and hexacarboxyl porphyrin are mostly isomer III; and pentacarboxyl porphyrin and coproporphyrin are approximately equal mixtures of isomers I and III.

Diagnosis and Differential Diagnosis

Plasma porphyrins are always increased in clinically manifest PCT, and a total plasma porphyrin determination is useful for screening. A normal value rules out PCT and other porphyrias that produce blistering skin lesions. If increased, it is useful to determine the plasma fluorescence emission maximum at neutral pH, because a maximum near 619 nm is characteristic of PCT (as well as CEP and HCP) and importantly, excludes VP, which has a distinctly different fluorescence maximum. Increased urinary or plasma porphyrins, with a predominance of uroporphyrin and heptacarboxyl porphyrin, is confirmatory. Urine porphyrins are less useful for initial screening because nonspecific increases, especially of coproporphyrin, occur in liver disease and other medical conditions. Urinary ALA may be increased slightly, and PBG is normal. Mild cases of CEP can mimic PCT clinically, and this possibility is ruled out by finding normal or only mildly increased levels of erythrocyte porphyrins.

Familial (type 2) can be distinguished from sporadic (type 1) PCT by finding decreased erythrocyte UROD activity (in type 2), or more reliably by finding a disease-related *UROD* mutation. Type 3 is distinguished from type 1 only by occurrence of PCT in a relative. Biochemical findings in HEP are similar to those in PCT, but with an additional marked increase in erythrocyte zinc protoporphyrin.

Pseudoporphyria (also known as pseudo-PCT) presents with skin lesions that closely resemble PCT, but without significant increases in plasma porphyrins. A photosensitizing agent such as a nonsteroidal antiinflammatory drug (NSAID) is sometimes implicated. Both PCT and pseudoporphyria may occur in patients with ESRD.

Complications

Cutaneous blisters may rupture and become infected, sometimes leading to cellulitis. In more-severe disease in patients with ESRD, repeated infections can be mutilating, as in CEP. **Pseudoscleroderma** , with scarring, contraction, and calcification of skin and subcutaneous tissue, is a rare complication. Other complications include advanced liver disease and hepatocellular carcinoma.

Treatment

Two specific and effective forms of treatment, phlebotomy and low-dose hydroxychloroquine, are available. Susceptibility factors should be removed when possible. The diagnosis of PCT must be firmly established because conditions that produce identical cutaneous lesions do not respond to these treatments. Treatment can usually be started after demonstrating an increase in plasma total porphyrins and excluding VP by analysis of the fluorescence spectrum at neutral pH, while urine and fecal studies are still pending. Use of alcohol, estrogens (in women), and smoking should be stopped and patients tested for HCV, HIV, and *HFE* mutations. Susceptibility factors and degree of iron overload, as assessed by the serum ferritin concentration, can influence the choice of treatment.

Phlebotomy is considered standard therapy and is effective in both children and adults with PCT because it reduces hepatic iron content. Treatment is guided by plasma (or serum) ferritin and porphyrin levels. Hemoglobin or hematocrit levels should be followed to prevent symptomatic anemia. For adults, a unit of blood (450 mL) is removed at about 2 wk intervals until a target serum ferritin near the lower limit of normal (15 ng/mL) is achieved. A total of 6-8 phlebotomies is often sufficient in adults. After this, plasma porphyrin concentrations continue to fall from pretreatment levels (generally 10-25 µg/dL) to below the upper limit of normal (1 µg/dL), usually after several more weeks. This is followed by gradual clearing of skin lesions, sometimes including pseudoscleroderma. Liver function abnormalities may improve, and hepatic siderosis, needle-like inclusions, and red fluorescence of liver tissue will disappear. Although remission usually persists even if ferritin levels later return to normal, it is advisable to follow porphyrin levels and reinstitute phlebotomies if porphyrins begin to increase. Infusions of deferoxamine, an iron chelator, may be used when phlebotomy is contraindicated.

An alternative when phlebotomy is contraindicated or poorly tolerated is a low-dose regimen of **hydroxychloroquine** (or chloroquine). Normal doses of these 4-aminoquinoline antimalarials in PCT increase plasma and urinary porphyrin levels and increase photosensitivity, reflecting an outpouring of porphyrins from the liver. This is accompanied by acute hepatocellular damage, with fever, malaise, nausea, and increased serum transaminases, but is followed by complete remission of the porphyria. These adverse consequences of normal doses are largely avoided by a low-dose regimen (for adults, hydroxychloroquine 100 mg or chloroquine 125 mg, i.e., half a normal tablet, twice weekly), which can be continued until plasma or urine porphyrins are normalized. In young children, half the adult dose is recommended. There is at least some risk of retinopathy, which may be lower with hydroxychloroquine. The mechanism of action of 4-aminoquinolines in PCT is not known but is quite specific, because these drugs are not useful in other porphyrias. Recent studies indicate that low-dose hydroxychloroquine is as safe and effective as phlebotomy in adults with PCT.

In patients with PCT and hepatitis C, PCT should be treated first because this condition is more symptomatic and can be treated more quickly and effectively. Treatment of PCT by phlebotomy may not be possible once interferon-ribavirin treatment is complicated by anemia. Moreover, treatment of hepatitis C may be more effective after iron reduction. Whether direct-acting antiviral agents should be used initially for treating both hepatitis C and PCT is under investigation.

PCT in patients with ESRD is often more severe and difficult to treat. However, erythropoietin administration can correct anemia, mobilize iron, and support phlebotomy in many cases. Improvement after renal transplantation may be partly from resumption of endogenous erythropoietic production.

Liver imaging and a serum α-fetoprotein determination may be advisable in all PCT patients, perhaps at 6-12 mo intervals, for early detection of hepatocellular carcinoma. Finding low-erythrocyte UROD activity or a *UROD* mutation identifies those with an underlying genetic predisposition, which does not alter treatment but is useful for genetic counseling.

Prognosis

Porphyria cutanea tarda is the most readily treated form of porphyria, and complete remission is expected with treatment either by phlebotomy or low-dose hydroxychloroquine. There is little information on rates of recurrence and long-term outlook. Risk for hepatocellular carcinoma is increased, and some susceptibility factors such as hepatitis C can lead to complications even after PCT is in remission.

Prevention and Genetic Counseling

A heritable *UROD* mutation can usually be detected or excluded by measuring erythrocyte UROD activity, although DNA studies are more sensitive. Relatives of patients with *UROD* mutations have an increased risk for developing PCT and may have increased motivation to avoid adverse behaviors such as ethanol and tobacco use and exposures to HCV and HIV (although such counseling would be given to anyone). The finding of *HFE* mutations, and especially C282Y, should prompt screening of relatives, some of whom may be C282Y homozygotes and warrant lifelong monitoring of serum ferritin.

Hepatoerythropoietic Porphyria

HEP is the homozygous form of familial (type 2) PCT; it resembles CEP clinically. Excess porphyrins originate mostly from liver, with a pattern consistent with severe UROD deficiency. This rare disorder has no particular racial predominance.

Etiology

HEP is an autosomal recessive disorder, and most patients have inherited a different mutation from unrelated parents. In contrast to most mutations in familial PCT, most causing HEP are associated with expression of some residual enzyme activity. At least 1 genotype is associated with the predominant excretion of pentacarboxyl porphyrin.

Pathology and Pathogenesis

Excess porphyrins originate primarily from the liver in HEP, although the substantial increase in erythrocyte zinc protoporphyrin indicates that the heme biosynthetic pathway is also impaired in bone marrow erythroid cells. Apparently, porphyrinogens accumulate in the marrow while hemoglobin synthesis is most active and are metabolized to protoporphyrin after hemoglobin synthesis is complete. The cutaneous lesions are a result of photoactivation of porphyrins in skin, as in other cutaneous porphyrias.

Clinical Manifestations

As in CEP, this disease usually presents with blistering skin lesions, hypertrichosis, scarring, and red urine in infancy or childhood. *Sclerodermoid* skin changes are sometimes prominent. Unusually mild cases have been described. Concurrent conditions that affect liver function can alter disease severity; the disease manifested because of hepatitis A in a 2 yr old child and then improved with recovery of liver function.

Laboratory Findings

Biochemical findings resemble those in PCT, with accumulation and excretion of uroporphyrin, heptacarboxyl porphyrin, and isocoproporphyrin. In addition, erythrocyte zinc protoporphyrin is substantially increased.

Diagnosis and Differential Diagnosis

HEP is distinguished from CEP by increases in both uroporphyrin and heptacarboxyl porphyrin, and isocoproporphyrins. In CEP, the excess erythrocyte porphyrins are predominantly uroporphyrin I and coproporphyrin I rather than protoporphyrin. Blistering skin lesions are unusual in EPP, the excess erythrocyte protoporphyrin in that disease is metal free and not complexed with zinc, and urinary porphyrins are normal.

Treatment and Prognosis

Avoiding sunlight exposure is most important in managing HEP, as in CEP. Oral charcoal was helpful in a severe case associated with dyserythropoiesis. Phlebotomy has shown little or no benefit. The outlook depends on the severity of the enzyme deficiency and may be favorable if sunlight can be avoided.

Prevention and Genetic Counseling

As part of genetic counseling in affected families, it is feasible to diagnose HEP in utero, either by analysis of porphyrins in amniotic fluid or DNA studies.

Hereditary Coproporphyria

This autosomal dominant hepatic porphyria is caused by a deficiency of coproporphyrinogen oxidase (CPOX). The disease presents with acute attacks, as in AIP. Cutaneous photosensitivity may occur, but much less often than in VP. Rare homozygous cases present in childhood.

Etiology

A partial (50%) deficiency in CPOX activity has been found in all cells studied from patients with HCP. A much more profound deficiency is found in homozygous cases. Human CPOX is a homodimer composed of 39 kDa subunits and contains no metals or prosthetic groups. The enzyme requires molecular oxygen and is localized in the mitochondrial intermembrane space. A single active site on the enzyme catalyzes the oxidative decarboxylation of 2 of the 4 propionic acid groups of coproporphyrinogen III to form the 2 vinyl groups at positions 2 and 4, on rings A and B, respectively, of protoporphyrinogen IX. Most of the intermediate tricarboxyl porphyrinogen, termed *harderoporphyrinogen*, is not released before undergoing the 2nd decarboxylation to protoporphyrinogen IX. Coproporphyrinogen I is not a substrate for this enzyme.

The human *CPOX* gene contains 7 exons and is located on chromosome 3q12.1. A single promoter contains elements for both housekeeping and erythroid-specific expression. A variety of *CPOX* mutations have been described in HCP, with a predominance of missense mutations and no genotype-phenotype correlations. **Harderoporphyria** , an autosomal recessive biochemical variant form of HCP, is caused by *CPOX* mutations that impair substrate binding, leading to premature release of harderoporphyrinogen.

Epidemiology

HCP is less common than AIP and VP, but its prevalence has not been carefully estimated. There is no obvious racial predominance. Homozygous HCP is rare and presents during childhood. Harderoporphyria, a biochemically distinguishable variant of HCP, has been recognized in heteroallelic and homoallelic forms.

Pathology and Pathogenesis

Increased ALA and PBG during acute attacks of HCP may be explained by induction of ALAS1 and by the normally relatively low activity of PBGD in the liver. Hepatic ALAS1 is increased during acute attacks but is normal when the disease is latent and porphyrin precursor excretion is normal. Because coproporphyrinogen III concentration in the liver is probably less than the K_m for CPOX, the reaction rate is likely to be determined in part by substrate concentration. The substrate coproporphyrinogen appears to be lost more readily from the liver cell than, for example, uroporphyrinogen, especially when heme synthesis is stimulated. Coproporphyrin and coproporphyrinogen are both transported into bile and excreted in urine, and do not appear to accumulate in the liver in HCP.

Clinical Manifestations

Symptoms are identical to those of AIP except that attacks are generally milder, and cutaneous lesions that resemble those in PCT develop occasionally. Severe motor neuropathy and respiratory paralysis can occur. As in other acute porphyrias, HCP is almost always latent before puberty, and symptoms are most common in adult women. Attacks are precipitated by the same factors that cause attacks in AIP, including fasting, OCs, and hormone increases during the luteal phase of the menstrual cycle. Concomitant liver diseases may increase porphyrin retention and photosensitivity. The risk of hepatocellular carcinoma is increased, as in other acute porphyrias.

The clinical features of homozygous HCP or harderoporphyria begin in early childhood and include jaundice, hemolytic anemia, hepatosplenomegaly, and skin photosensitivity. These symptoms are generally quite distinct from those seen in heterozygotes. Hematologic features are particularly characteristic in harderoporphyria.

Laboratory Findings

The porphyrin precursors ALA and PBG are increased during acute attacks in HCP but may decrease more rapidly than in AIP. Marked increases in coproporphyrin III in urine and feces are more persistent in HCP. In homozygous cases, porphyrin excretion may be more increased and is accompanied by substantial increases in erythrocyte zinc protoporphyrin. Harderoporphyria is characterized by a marked increase in fecal excretion of harderoporphyrin (tricarboxyl porphyrin) as well as coproporphyrin. Plasma porphyrins are usually normal or only slightly increased.

Diagnosis and Differential Diagnosis

The diagnosis of HCP is readily established in patients with clinically manifest disease, although urinary ALA, PBG, and uroporphyrin may revert to normal more quickly than in AIP. Urinary coproporphyrin III is increased. Urinary porphyrins, especially coproporphyrin, can be increased in many medical conditions (e.g., liver disease), and small increases that are not diagnostically significant may lead to an incorrect diagnosis of HCP. Fecal porphyrins are mostly coproporphyrin (isomer III) in HCP, whereas in VP, coproporphyrin III and protoporphyrin are often increased approximately equally. Plasma porphyrins are usually normal in HCP and increased in VP.

The ratio of fecal coproporphyrin III to coproporphyrin I is especially sensitive for detecting latent heterozygotes (especially adults). Assays for CPOX, a mitochondrial enzyme, require cells such as lymphocytes and are not widely available. Identification of a *CPOX* mutation in an index case greatly facilitates screening family members.

Treatment and Prognosis

Acute attacks of HCP are treated as in AIP, which includes IV hemin and identifying and avoiding precipitating factors. Cholestyramine may be of some value for photosensitivity occurring with liver dysfunction. Phlebotomy and chloroquine are not effective. GnRH hormone analogs can be effective for prevention of cyclic attacks. The prognosis is generally better than in AIP.

Prevention and genetic counseling are the same as in other acute porphyrias.

Variegate Porphyria

This hepatic porphyria is caused by a deficiency of protoporphyrinogen oxidase (PPOX), which is inherited as an autosomal dominant trait. The disorder is termed *variegate* because it can present with neurologic or cutaneous manifestations, or both. Other terms have included *porphyria variegata, protocoproporphyria,* and *South African genetic porphyria*. Rare cases of homozygous VP are symptomatic in childhood.

Etiology

PPOX is approximately half normal in all cells studied in patients with VP. The enzyme is more markedly deficient in rare cases of homozygous VP, with approximately half-normal enzyme activity in parents.

Human PPOX is a homodimer that contains flavin adenine dinucleotide and is localized to the cytosolic side of the inner mitochondrial membrane. Membrane-binding domains may be docked onto human FECH, the next enzyme in the pathway, which is embedded in the opposite side of the membrane. PPOX catalyzes the oxidation of protoporphyrinogen IX to protoporphyrin IX by the removal of 6 hydrogen atoms. The enzyme requires molecular oxygen. The substrate is readily oxidized nonenzymatically to protoporphyrin under aerobic conditions, or if exported into the cytosol. PPOX is highly specific for protoporphyrinogen IX and is inhibited by tetrapyrroles such as heme, biliverdin, and bilirubin and by certain herbicides that cause protoporphyrin to accumulate and induce phototoxicity in plants. Inhibition by bilirubin may account for decreased PPOX activity in Gilbert disease.

The human *PPOX* gene on chromosome 1q22-q23 consists of 1 noncoding and 12 coding exons. A single PPOX transcript is produced in a variety of tissues, but putative transcriptional element binding sequences may allow for erythroid-specific expression. Many *PPOX* mutations have been reported in VP families. A missense mutation, R59W, is prevalent in South Africa. No convincing genotype-phenotype correlations have been identified. Mutations in homozygous cases of VP are more likely to encode enzyme proteins with residual activity.

Epidemiology

VP is less common than AIP in most countries. The R59W mutation is highly prevalent in South African whites (3 in 1,000 in this population). This example of “genetic drift” or founder effect has been traced to a man or his wife who emigrated from Holland to South Africa in 1688. In Finland, prevalence is 1.3 in 100,000 people and is about as common as AIP.

Pathology and Pathogenesis

Acute attacks develop in a minority (approximately 25%) of heterozygotes for PPOX deficiency and are often attributable to drugs, steroids, and nutritional factors that play a role in other acute porphyrias. Protoporphyrinogen IX accumulates and undergoes autoxidation to protoporphyrin IX. Coproporphyrinogen III accumulates, perhaps as the result of a close functional association between PPOX in the inner mitochondrial membrane and CPOX in the intermembrane space. Liver porphyrin content is not increased. The increased porphyrin content in plasma consists of porphyrin-peptide conjugates, which may be formed from protoporphyrinogen. Increased ALA and PBG during acute attacks may be explained, as in HCP, by induction of ALAS1 by exacerbating factors, and by the normally relatively low activity of PBGD in liver. Furthermore, PBGD is inhibited by protoporphyrinogen, the substrate for PPOX.

Clinical Manifestations

Symptoms develop in some heterozygotes after puberty. Neurovisceral symptoms occurring as acute attacks are identical to AIP but are generally milder and less often fatal. Drugs, steroids, and nutritional alterations such as fasting, which are harmful in AIP, can also induce attacks of VP. Attacks occur equally in males and females, at least in South Africa. Cutaneous fragility, vesicles, bullae, hyperpigmentation, and hypertrichosis of sun-exposed areas are much more common than in HCP. They are likely to occur apart from and to be longer lasting than the neurovisceral symptoms. OCs can precipitate cutaneous manifestations. Acute attacks have become less common, and skin manifestations are more frequently the initial presentation; this may result from earlier diagnosis and counseling. The risk of hepatocellular carcinoma is increased.

Symptoms of homozygous VP begin in infancy or childhood. These children generally have severe photosensitivity, neurologic symptoms, seizures, developmental disturbances, and sometimes growth retardation, but they do not have acute attacks.

Laboratory Findings

Urinary ALA, PBG, and uroporphyrin are increased during acute attacks, but often less so than in AIP, and may be normal or only slightly increased during remission. Plasma porphyrins, urinary coproporphyrin III, and fecal coproporphyrin III and protoporphyrin are more persistently increased between attacks. Erythrocyte zinc protoporphyrin levels are greatly increased in homozygous VP and may be modestly increased in heterozygous cases.

Diagnosis and Differential Diagnosis

VP is readily distinguished biochemically from AIP and HCP, which also present with acute attacks and increases in PBG. Plasma porphyrin analysis is especially useful because the plasma porphyrins in VP are tightly protein bound, resulting in a characteristic fluorescence emission spectrum at neutral pH. Fecal porphyrins are increased, with approximately equal amounts of coproporphyrin III and protoporphyrin. Fluorometric detection of plasma porphyrins is more sensitive than stool porphyrin analysis in asymptomatic VP. PPOX assays using cells that contain mitochondria, such as lymphocytes, are sensitive for identifying asymptomatic carriers but are not widely available. Knowing the *PPOX* mutation in an index case enables the identification of relatives who carry the same mutation.

Treatment

Acute attacks are treated as in AIP. Hemin is beneficial for acute attacks but not for cutaneous symptoms. Light protection is important in patients with skin manifestations, using long-sleeved clothing, gloves, a broad-brimmed hat, and opaque sunscreen preparations. Exposure to short-wavelength UV light, which does not excite porphyrins, may increase skin pigmentation and provide some protection. Phlebotomy and chloroquine are not effective. Surprisingly, oral activated charcoal was reported to increase porphyrin levels and worsen skin manifestations.

Prognosis and Prevention

The outlook of patients with VP has improved, which may be attributed to improved treatment, earlier diagnosis, and detection of latent cases. Cyclic acute attacks in women can be prevented with a GnRH analog, as in AIP. A diagnosis of VP or any other acute porphyria should not lead to difficulty obtaining insurance, because the prognosis is usually good once the diagnosis is established.

Genetic counseling is the same as in other acute porphyrias.

Erythropoietic Protoporphyria and X-Linked Protoporphyria

These forms of protoporphyria are genetically distinct but have essentially the same phenotype. In EPP, an autosomal recessive disorder, protoporphyrin accumulates as the result of a marked deficiency of FECH, the last enzyme in the heme biosynthetic pathway, because of *FECH* mutations. EPP is sometimes termed *erythrohepatic protoporphyria*, although the liver does not contribute substantially to production of excess protoporphyrin in uncomplicated cases. XLP is the most recently described porphyria, in which gain-of-function *ALAS2* mutations leads to overproduction of ALA in the marrow, where it is metabolized to excess amounts of protoporphyrin.

Etiology

Ferrochelatase (FECH), the enzyme that is deficient in EPP, catalyzes the final step in heme synthesis, which is insertion of ferrous iron (Fe^{2+}) into protoporphyrin IX (see Fig. 110.1). The enzyme is also termed *heme synthetase* or *protoheme ferrolyase.* The human enzyme is a dimer, and each homodimer contains a [2Fe-2S] cluster, which may have a role in bridging homodimers. FECH is found in the mitochondrial inner membrane, where its active site faces the mitochondrial matrix. It may be associated with complex I of the mitochondrial electron transport chain, and the ferrous iron substrate may be produced on nicotinamide adenine dinucleotide oxidation. FECH is specific for the reduced form of iron but can utilize other metals, such as Zn^{2+} and Co^{2+} , and other dicarboxyl porphyrins. Accumulation of free protoporphyrin rather than zinc protoporphyrin in EPP indicates that formation of the latter is dependent on FECH activity in vivo.

The human *FECH* gene is located on chromosome 18q21.3, has a single promoter sequence, and contains 11 exons. Two mRNAs of 1.6 and 2.5 kb were described, which may be explained by the use of 2 alternative polyadenylation signals. The larger transcript is more abundant in murine erythroid cells, suggesting erythroid-specific regulation of FECH. A variety of *FECH* mutations have been reported in EPP, including missense, nonsense, and splicing mutations; small and large deletions; and an insertion.

The inheritance of 2 alleles associated with reduced FECH activity is required for disease expression. This is consistent with FECH activities as low as 15–25% of normal in EPP patients. In most patients, a pathogenic mutation on 1 *FECH* allele is combined with a common variant affecting the other allele. This common variant *FECH* allele (IVS3-48T>C) produces less-than-normal amounts of enzyme because it expresses an aberrantly spliced mRNA that is degraded by a nonsense-mediated RNA decay mechanism. The IVS3-48T > C *FECH* variant by itself does not cause disease, even when homozygous. In a few families, 2 severe *FECH* mutations have been found, without the IVS3-48T> C allele.

EPP with autosomal recessive inheritance occurs naturally in cattle and in mouse models.

XLP is associated with gain-of-function deletions in the last exon of *ALAS2* . These lesions delete the last 10-20 amino acids of the ALAS2 polypeptide and apparently make the enzyme more stable. Metal-free protoporphyrin predominates in erythrocytes in these cases, but because FECH activity is normal, the proportion of zinc protoporphyrin is greater than in classic EPP. XLP accounts for approximately 2% of cases with the EPP phenotype in Europe and approximately 10% of cases in North America.

EPP is sometimes associated with **myelodysplastic syndromes** and expansion of a clone of hematopoietic cells with deletion of 1 *FECH* allele or with other

FECH mutations. In such cases there is late onset of the disease.

Epidemiology

EPP is the most common porphyria to cause symptoms in children but is often not diagnosed until adult life. Overall it is the 3rd most common porphyria, although its prevalence is not precisely known (see Table 110.2). It is described mostly in white people but occurs in other races. The IVS3-48T>C splice variant is common in whites and Japanese but rare in Africans, which explains lower disease prevalence in populations of African origin.

Pathology and Pathogenesis

FECH is deficient in all tissues in EPP, but bone marrow reticulocytes are thought to be the primary source of the excess protoporphyrin, some of which enters plasma and circulates to the skin. Circulating erythrocytes are no longer synthesizing heme and hemoglobin, but they contain excess free protoporphyrin, which also contributes. In XLP caused by terminal deletions in exon 11 of *ALAS2* , all intermediates of the heme pathway are overproduced and ultimately accumulate in bone marrow erythroblasts as protoporphyrin. FECH is not deficient in XLP, so this enzyme chelates some of the excess protoporphyrin with zinc. An aberrantly spliced mitoferrin transcript, which limits iron transport into mitochondria, has also been described in XLP. The liver functions as an excretory organ rather than a major source for excess protoporphyrin. FECH deficiency in the skin and liver may be important, however, because tissue transplantation studies in mice suggest that skin photosensitivity and liver damage occur only when FECH is deficient in these tissues.

Patients with EPP and XLP are maximally sensitive to light in the 400 nm range, which corresponds to the so-called Soret band, the narrow peak absorption maximum that is characteristic for protoporphyrin and other porphyrins. Having absorbed light, porphyrins enter an excited energy state and release energy as fluorescence, singlet oxygen, and other ROS. Resulting tissue damage is accompanied by lipid peroxidation, oxidation of amino acids, cross linking of proteins in cell membranes, and damage to capillary endothelial cells. Such damage may be mediated by photoactivation of the complement system and release of histamine, kinins, and chemotactic factors. Repeated acute damage leads to thickening of the vessel walls and perivascular deposits from accumulation of serum components. Deposition of amorphous material containing immunoglobulin, complement components, glycoproteins, acid glycosaminoglycans, and lipids occurs around blood vessels in the upper dermis.

There is little evidence for impaired erythropoiesis or hemolysis in EPP. However, mild anemia with microcytosis, hypochromia, and reticulocytosis is common. Iron accumulation in erythroblasts and ring sideroblasts has been noted in bone marrow in some patients. Decreased transferrin saturation and low or low-normal serum ferritin suggest iron deficiency. Iron status should be carefully evaluated in EPP patients, keeping in mind that iron deficiency may lead to further increases in protoporphyrin and increase the risk for cholestasis. Poor response to oral iron supplements is described in EPP and is unexplained. Some patients report increased photosensitivity when given iron supplements, but whether this is from transient increases in porphyrins when iron deficiency is corrected and erythropoiesis increases is not known. Case reports suggest that iron supplementation decreases protoporphyrin and improves anemia, especially in patients with XLP.

Liver damage develops in a small proportion of EPP and XLP patients and is attributed to excess protoporphyrin, which is insoluble in water and excreted only by hepatic uptake, and biliary excretion is cholestatic. Some may be reabsorbed by the intestine and undergo enterohepatic circulation. With cholestasis the excess protoporphyrin that accumulates in the liver can form crystalline structures in hepatocytes and impair mitochondrial function.

Clinical Manifestations

Symptoms of cutaneous photosensitivity begin in childhood and consist of acute pain and itching often occurring within minutes of sunlight exposure and followed by redness and swelling with continued exposure (Fig. 110.7). Petechiae and purpuric lesions may be seen, but blisters are rare. Swelling may resemble angioneurotic edema and *solar urticaria*. Symptoms are usually worse in the spring and summer. Chronic changes may include lichenification, leathery pseudovesicles, labial grooving, and nail changes, but changes in pigmentation and pronounced scarring are unusual. Although physical findings in EPP and XLP may not be impressive, the symptoms significantly impair quality of life to a greater extent than in PCT or VP. An association between EPP caused by mutations affecting both FECH alleles and seasonal palmar keratoderma is unexplained. Neuropathy develops only in some patients with severe hepatic decompensation. XLP males have a more severe phenotype with higher protoporphyrin levels than most EPP patients. XLP females have a variable clinical presentation—some with no symptoms or mild symptoms and others with severe symptoms similar to XLP males. This variability in females is likely the result of random X-chromosome inactivation.

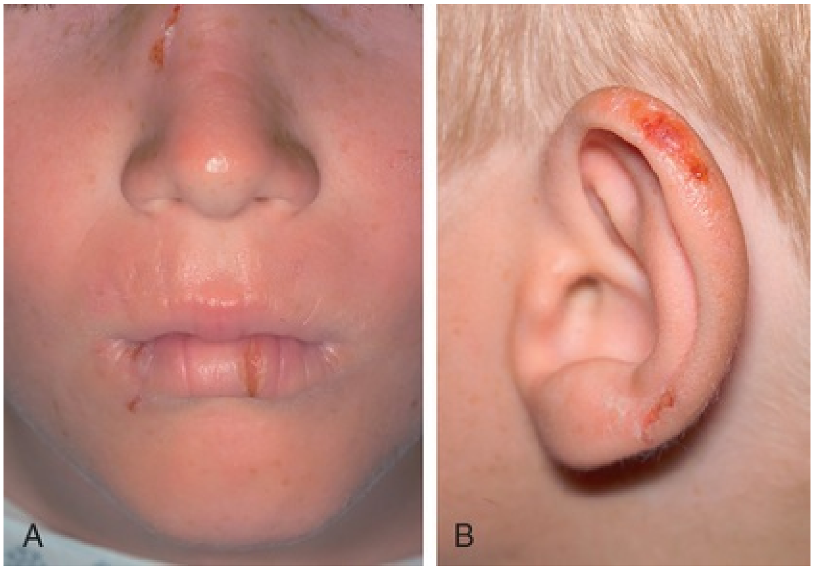

FIG. 110.7 Erythropoietic protoporphyria (EPP). A, Linear erosions of the lateral nasal bridge and lower lip in a patient with EPP. B, Erosions with crusting on the left helix of a patient with EPP. (From Horner ME, Alikhan A, Tintle S, et al: Cutaneous porphyrias. Part 1. epidemiology, pathogenesis, presentation, diagnosis, and histopathology, *Int J Dermatol* 52:1464–1480, 2013, Figs 7 and 8, p 1473.)

Unless hepatic or other complications develop, protoporphyrin levels and symptoms of photosensitivity remain remarkably stable for many years in most patients. Factors that exacerbate hepatic porphyrias play little or no role in EPP or XLP. Erythrocyte protoporphyrin levels may decrease and sunlight tolerance may improve during pregnancy, which is unexplained.

Laboratory Findings

Protoporphyrin is substantially increased in circulating erythrocytes in EPP and consists almost entirely of free protoporphyrin. In XLP, both zinc protoporphyrin and free protoporphyrin are increased, although the latter still predominates. Protoporphyrin is also increased in bone marrow, plasma, bile, and feces. Other porphyrins and porphyrin precursors are normal in uncomplicated EPP and XLP.

Diagnosis and Differential Diagnosis

A diagnosis of EPP is confirmed biochemically by finding a substantially elevated concentration of total erythrocyte protoporphyrin, which is predominantly (at least 85%) metal free and not complexed with zinc. In XLP, both free and zinc-complexed protoporphyrins are elevated. Erythrocyte total protoporphyrin levels are on average higher in XLP and more variable between individuals with EPP, possible reflecting differences in severity of the many reported *FECH* mutations. Erythrocyte zinc protoporphyrin concentration is increased with little increase in metal-free protoporphyrin in homozygous porphyrias (except CEP), iron deficiency, lead poisoning, anemia of chronic disease, hemolytic conditions, and many other erythrocytic disorders. Measurement of FECH activity requires cells containing mitochondria and is not widely available.

Plasma total porphyrin concentration is often less increased in EPP than in other cutaneous porphyrias and may be normal. Great care must be taken to avoid light exposure during sample processing, because plasma porphyrins in EPP are particularly subject to photodegradation. Urinary porphyrin precursors and porphyrins are not increased.

DNA studies are strongly recommended for confirming *FECH* or *ALAS2* mutations and for genetic counseling.

Life-threatening **protoporphyric hepatopathy** is characterized by greater increases in erythrocyte and plasma protoporphyrin levels, increased photosensitivity and either chronically abnormal liver function tests or rapidly progressive hepatic failure. Presumably this is heralded by increases above the patient's baseline erythrocyte and plasma porphyrin levels, but this has not been documented, because most such patients have not had adequate baseline determinations of porphyrin values. Increases in urinary porphyrins, especially coproporphyrin, in this setting are attributable to liver dysfunction.

Complications

There is an increased risk of biliary stones, which contain protoporphyrin and are sometimes symptomatic, requiring cholecystectomy. Protoporphyric hepatopathy occurs in <5% of protoporphyria patients, including children, and may be chronic or progress rapidly to death from liver failure. This liver disease is sometimes the major presenting feature of EPP. In XLP, liver disease may be more frequent, and in one report of 8 families, 17% of patients had overt liver dysfunction. Protoporphyric hepatopathy can cause acute upper abdominal pain suggesting biliary obstruction, and unnecessary laparotomy to exclude this possibility can be detrimental. Concurrent conditions that impair liver function, such as viral hepatitis, alcohol- or drug-induced liver disease, or OCs may contribute. Whether iron deficiency may contribute is unclear. Liver histology shows marked deposition of protoporphyrin as inclusions in liver cells and bile canaliculi. Patients with protoporphyric liver failure most often have *FECH* “null mutations” and the IVS3–48T>C hypoexpression allele, but some may have 2 severe mutant *FECH* alleles or XLP caused by *ALAS2* exon 11 deletions. The bone marrow is probably the major source of protoporphyrin, even in EPP patients with hepatic failure.

Treatment

Exposure to sunlight should be avoided, which is aided by wearing closely woven clothing. A systematic review of treatment options, including beta-carotene, oral cysteine, and vitamin C, showed no proven efficacy of these treatments. One report suggested that high doses of cimetidine were effective in reducing symptoms in 3 children with EPP, but no objective clinical evidence of efficacy was presented.

Measures to darken the skin may also be helpful. This may be accomplished by narrow-band UV-B phototherapy. Double-blind, placebo-controlled studies in the United States and Europe of **afamelanotide** , a synthetic analog of melanocyte-stimulating hormone, showed an increase in pain-free sun exposure and improved quality of life in patients with protoporphyria. This drug is approved for adult use in Europe and is pending U.S. Food and Drug Administration (FDA) approval, and studies in children are anticipated.

Drugs or hormone preparations that impair hepatic excretory function should be avoided, particularly in patients with liver dysfunction, and iron deficiency should be corrected if present, especially in XLP. Vitamin D supplementation and hepatitis A and B vaccination are recommended.

Treatment of protoporphyric hepatopathy must be individualized, and results are unpredictable. Ursodeoxycholic acid may be of some value in early stages. Cholestyramine or activated charcoal may interrupt the enterohepatic circulation of protoporphyrin, promote its fecal excretion, and reduce liver protoporphyrin content. Spontaneous resolution may occur, especially if another reversible cause of liver dysfunction, such as viral hepatitis or alcohol abuse, is contributing. In patients with severe hepatic decompensation, combined treatment with plasmapheresis, transfusion to correct anemia and suppress erythropoiesis, IV hemin to suppress erythroid and possibly hepatic protoporphyrin production, ursodeoxycholic acid, vitamin E, and cholestyramine may be beneficial and bridge patients to liver transplantation.

Motor neuropathy resembling that seen in acute porphyrias sometimes develops in protoporphyria patients with liver disease before or after transfusion or liver transplantation and is sometimes reversible. Artificial lights, such as operating room lights during liver transplantation or other surgery, may cause severe photosensitivity, with extensive burns of the skin and peritoneum and damage to circulating erythrocytes.

Although liver disease may recur in the transplanted liver as a result of continued bone marrow production of excess protoporphyrin, outcomes are comparable to transplantation for other types of liver disease. Bone marrow transplantation should also be considered after liver transplantation if a suitable donor is available.

Prognosis

Typical EPP patients have lifelong photosensitivity but can otherwise expect normal longevity. Protoporphyric liver disease is often life-threatening; however, the incidence is low.

Prevention and Genetic Counseling

Symptoms can be prevented by avoiding sunlight. Avoiding agents that may cause liver damage may help prevent liver complications. Opinions vary on the value of iron replacement, and this is currently under study.

DNA studies to identify *FECH* mutations, the common IVS3–48T>C *FECH* hypoexpression allele, or *ALAS2* exon 11 deletions are important for genetic counseling. When EPP is caused by a severe *FECH* mutation and the common IVS3–48T>C *FECH* allele, DNA studies in the spouse to determine the presence, or more likely the absence, of the hypoexpression allele can predict whether offspring are at risk for EPP. EPP may improve during pregnancy.

Dual Porphyria

An unusual pattern of porphyrin precursors and porphyrins may suggest mutations of 2 heme pathway enzymes, as documented in 2 patients. One presented with acute porphyria and had heterozygous mutations of both *CPOX* and *ALAD* . The other had symptoms of AIP and PCT and was reported to have both *HMBS* and *UROD* mutations. In other reported cases, 1 or both enzyme deficiencies were based on enzyme measurements.

Porphyria Resulting From Tumors

Very rarely, hepatocellular tumors contain and presumably produce excess porphyrins, but such cases have not been studied carefully. Hepatocellular carcinomas complicating PCT and acute hepatic porphyrias usually are not described as containing large amounts of porphyrins. Erythropoietic porphyrias can develop late in life from clonal expansion of erythroid cells containing a specific enzyme deficiency in patients who have developed myelodysplastic or myeloproliferative syndromes.

[*] Hemin is the generic name for all heme preparations used for intravenous administration. Hemin is also a chemical term that refers to the oxidized (ferric) form of heme (iron protoporphyrin IX) and is usually isolated as hemin chloride. In alkaline solution, the chloride is replaced by the hydroxyl ion, forming hydroxyheme, or hematin.

CHAPTER 111

Hypoglycemia

Mark A. Sperling

Glucose has a central role in fuel economy and is a source of energy storage in the form of glycogen, fat, and protein (see Chapter 105). As an immediate source of energy, glucose provides 38 mol of adenosine triphosphate (ATP) per mole of glucose oxidized. Glucose is essential for energy metabolism in the brain, where it is usually the preferred substrate and where its utilization accounts for nearly all the brain's oxygen consumption. Cerebral transport of glucose is a GLUT-1, carrier-mediated, facilitated diffusion process that is dependent on blood glucose concentration and not regulated by insulin. Therefore, low concentrations of blood glucose result in cerebral glucopenia. Deficiency of brain glucose transporters can result in seizures because of low cerebral and cerebrospinal fluid (CSF) glucose concentrations *(hypoglycorrhachia)* despite normal blood glucose levels. To maintain the blood glucose concentration and prevent it from falling precipitously to levels that impair brain function, an elaborate regulatory system has evolved.

The defense against hypoglycemia includes the autonomic nervous system and hormones that act in concert to enhance glucose production through enzymatic modulation of glycogenolysis and gluconeogenesis, while simultaneously limiting peripheral glucose utilization, which conserves glucose for cerebral metabolism. Hypoglycemia represents a defect in one or several of the complex interactions that normally integrate glucose homeostasis during feeding and fasting. This process is particularly important for neonates, in whom there is an abrupt transition from intrauterine life, characterized by dependence on transplacental glucose supply, to extrauterine life, characterized ultimately by the autonomous ability to maintain euglycemia. Because prematurity or placental insufficiency may limit tissue nutrient deposits, and genetic abnormalities in enzymes or hormones may become evident in the neonate, hypoglycemia is common in the neonatal period.

Definition

In neonates, there is not always an obvious correlation between blood glucose concentration and the classic clinical manifestations of hypoglycemia. The absence of symptoms does not indicate that glucose concentration is normal and has not fallen to less than some optimal level for maintaining brain metabolism. There is evidence that hypoxemia and ischemia may potentiate the role of hypoglycemia in causing permanent brain sequelae. Consequently, the lower limit of accepted normality of the blood glucose level in newborn infants with associated illness that already impairs cerebral metabolism has not been determined (see Chapter 127). Because of concern for possible neurologic, intellectual, or psychologic sequelae in later life, most authorities recommend that any value of blood glucose <55 mg/dL in neonates be viewed with suspicion, investigated, and vigorously treated if there are symptoms or it persists or recurs after a meal. This is particularly applicable after the initial 2-3 hr of life, when glucose normally has reached its nadir; subsequently, blood glucose levels begin to rise and achieve values of 55-65 mg/dL or higher after 12-24 hr. By day 3 of life in normal full-term newborns, blood glucose averages approximately 65 mg/dL (range 65-100). Therefore, in otherwise normal, full-term infants after day 3 of life and in older infants and children, a whole blood glucose concentration <55 mg/dL (10–15% higher for serum or plasma) represents hypoglycemia, because counter-regulatory mechanisms are activated at these glucose concentrations. In older children an idealized definition of hypoglycemia is based on “Whipple's Triad”; a plasma glucose concentration less than 60 mg/dL, together with concurrent CNS- or catecholamine-based symptoms, and resolution of symptoms when glucose concentration is restored to normal by treatment with glucose.

Significance and Sequelae

Most of the endogenous hepatic glucose production in infants and young children, which occurs several hours after feeding and during fasting, can be accounted for by brain metabolism.

Because the brain grows most rapidly in the 1st yr of life, and the larger proportion of glucose turnover is used for brain metabolism, sustained or repetitive hypoglycemia in infants and children can retard brain development and function. *Transient isolated and asymptomatic hypoglycemia of short duration does not appear to be associated with these severe sequelae.* In the rapidly growing brain, glucose may also be a source of membrane lipids and, together with protein synthesis, can provide structural proteins and myelination important for normal brain maturation. Under conditions of severe and sustained hypoglycemia, these cerebral structural substrates may become degraded to energy-usable intermediates such as lactate, pyruvate, amino acids, and ketoacids, which can support brain metabolism at the expense of brain growth. The capacity of the newborn brain to take up and oxidize ketone bodies is about 5-fold greater than that of the adult brain. However, the capacity of the liver to produce ketone bodies is limited in the immediate newborn period, especially in the presence of **hyperinsulinism** , which acutely inhibits hepatic glucose output, lipolysis, and ketogenesis, thereby depriving the brain of any alternate fuel sources. Although the brain may metabolize ketones, these alternate fuels cannot completely replace glucose as an essential central nervous system (CNS) fuel. The deprivation of the brain's major energy source during hypoglycemia and particularly the limited availability of alternate fuel sources during hyperinsulinism have predictable adverse consequences on brain metabolism and growth: decreased brain oxygen consumption and increased breakdown of endogenous structural components, with destruction of functional membrane integrity.

The major long-term sequelae of **severe, prolonged hypoglycemia** are cognitive impairment, recurrent seizure activity, cerebral palsy, and autonomic dysregulation. Subtle effects on personality are also possible but have not been clearly defined. Permanent neurologic sequelae are present in 25–50% of patients <6 mo old with severe recurrent symptomatic hypoglycemia. These sequelae may be reflected in pathologic changes characterized by reduced myelination in cerebral white matter and atrophy of the cerebral cortex, reflected in enlargement of the sulci and thinning of the gyri of the brain. These sequelae also are more likely when alternative fuel sources are limited, as occurs with hyperinsulinism, when the episodes of hypoglycemia are repetitive or prolonged, or when they are compounded by hypoxia. There is no precise knowledge relating the duration or severity of hypoglycemia to subsequent neurologic development of children in a predictable manner. Although less common, hypoglycemia in older children may also produce long-term neurologic defects through neuronal death mediated, in part, by cerebral excitotoxins released during hypoglycemia.

Substrate, Enzyme, and Hormonal Integration of Glucose Homeostasis

In the Newborn

Under nonstressed conditions, fetal glucose is derived entirely from the mother through placental transfer. Therefore, fetal glucose concentration usually reflects, but is slightly lower than, maternal glucose levels. Catecholamine release, which occurs with fetal stress such as hypoxia, mobilizes fetal glucose and free fatty acids (FFAs) through β-adrenergic mechanisms, reflecting β-adrenergic activity in fetal liver and adipose tissue. Catecholamines may also inhibit fetal insulin and stimulate glucagon release.

The acute interruption of maternal glucose transfer to the fetus at delivery imposes an immediate need to mobilize endogenous glucose. Three related events facilitate this transition: changes in hormones, changes in their receptors, and changes in key enzyme activity. There is a 3-5–fold abrupt increase in glucagon concentration within minutes to hours of birth. The insulin level usually falls initially and remains in the basal range for several days, without demonstrating the usual brisk response to physiologic stimuli such as glucose. A dramatic surge in spontaneous catecholamine secretion is also characteristic. Epinephrine can also augment growth hormone (GH) secretion by α-adrenergic mechanisms; GH levels are markedly elevated at birth. In addition, cortisol levels are higher in the immediate newborn period in infants born vaginally than by cesarean birth, in part reflecting the stress of labor on fetal cortisol secretion. Acting in concert, these hormonal changes at birth mobilize glucose by glycogenolysis and gluconeogenesis, activate lipolysis, and promote ketogenesis. As a result of these processes, plasma glucose concentration stabilizes after a transient decrease immediately after birth; liver glycogen stores become rapidly depleted within hours of birth; and gluconeogenesis from alanine, a major gluconeogenic amino acid, can account for approximately 10% of glucose turnover in the human newborn infant by several hours of age. FFA concentrations also increase sharply in concert with the surges in glucagon and epinephrine, followed later by rises in ketone bodies. Glucose is thus partially spared for brain utilization while FFAs and ketones provide alternative fuel sources for muscle as well as essential gluconeogenic factors such as acetyl-coenzyme A (CoA) and the reduced form of nicotinamide adenine dinucleotide from hepatic fatty acid oxidation, which is required to drive gluconeogenesis.

In the early postnatal period, responses of the endocrine pancreas favor glucagon secretion so that blood glucose concentration can be maintained. These adaptive changes in hormone secretion are paralleled by similarly striking adaptive changes in hormone receptors. Key enzymes involved in glucose production also change dramatically in the perinatal period. Thus, there is a rapid fall in glycogen synthase activity and a sharp rise in phosphorylase activity after delivery. Similarly, the activity of the rate-limiting enzyme for gluconeogenesis, phosphoenolpyruvate carboxykinase, rises dramatically after birth, activated in part by the surge in glucagon and the fall in insulin. This framework can explain several causes of neonatal hypoglycemia based on inappropriate changes in hormone secretion and unavailability of adequate reserves of **substrates** in the form of hepatic glycogen, **muscle** as a source of amino acids for gluconeogenesis, and **lipid** stores for the release of fatty acids. In addition, appropriate activities of key enzymes governing glucose homeostasis are required (see Fig. 105.1).

In Older Infants and Children

Hypoglycemia in older infants and children is analogous to that of adults, in whom glucose homeostasis is maintained by glycogenolysis in the immediate postfeeding period and by gluconeogenesis several hours after meals. The liver of a 10 kg child contains 20-25 g of glycogen, which is sufficient to meet normal glucose requirements of 4-6 mg/kg/min for only 6-12 hr. Beyond this period, hepatic gluconeogenesis must be activated. Both glycogenolysis and gluconeogenesis depend on the metabolic pathway summarized in Fig. 105.1 . Defects in glycogenolysis or gluconeogenesis may not be manifested in infants until the frequent feeding at 3-4 hr intervals ceases and infants sleep through the night, a situation usually present by 3-6 mo of age. The source of gluconeogenic precursors is derived primarily from muscle protein. The muscle bulk of infants and small children is substantially smaller relative to body mass than that of adults, whereas glucose requirements per unit of body mass are greater in children. Therefore the ability to compensate for glucose deprivation by gluconeogenesis is more limited in infants and young children, as is the ability to withstand fasting for prolonged periods. The ability of muscle to generate *alanine,* the principal gluconeogenic amino acid, may also be limited. Thus, in normal young children, the blood glucose level falls after 24 hr of fasting, insulin concentrations fall appropriately to levels of <5 µU/mL, lipolysis and ketogenesis are activated, and ketones may appear in the urine.

The switch from glycogen synthesis during and immediately after meals to glycogen breakdown and later gluconeogenesis is governed by hormones, with insulin of central importance. After a meal, plasma insulin concentrations increase to peak levels of 5-10–fold greater than their normal baseline concentration of approximately 5-10 µU/mL, which serves to lower the blood glucose concentration through the activation of glycogen synthesis, enhancement of peripheral glucose uptake, and inhibition of glucose production. In addition, lipogenesis is stimulated, whereas lipolysis and ketogenesis are curtailed. During fasting, plasma insulin concentrations fall to ≤5 µU/mL, and together with the rise of counter-regulatory hormones, this fall in insulin results in activation of gluconeogenic pathways (see Fig. 105.1). Fasting glucose concentrations are maintained through the activation of glycogenolysis and gluconeogenesis, inhibition of glycogen synthesis, and activation of lipolysis and ketogenesis. It should be emphasized that a plasma insulin concentration of >5 µU/mL, in association with a blood glucose concentration of ≤55 mg/dL (2.8-3.0 mM), is abnormal, indicating a state of excessive insulin action, termed *hyperinsulinism,* caused by failure of the mechanisms that normally result in suppression of insulin secretion during fasting or hypoglycemia.

The hypoglycemic effects of insulin are opposed by the actions of several hormones whose concentration in plasma increases as blood glucose falls. These counter-regulatory hormones—glucagon, growth hormone, cortisol, and epinephrine—act synergistically and in concert to increase blood glucose concentrations by activating glycogenolytic enzymes (glucagon, epinephrine); inducing gluconeogenic enzymes (glucagon, cortisol); inhibiting glucose uptake by muscle (epinephrine, growth hormone, cortisol); mobilizing amino acids from muscle for gluconeogenesis (cortisol); activating lipolysis and thereby providing glycerol for gluconeogenesis and fatty acids for ketogenesis (epinephrine, cortisol, GH, glucagon); and inhibiting insulin release and promoting GH and glucagon secretion (epinephrine).

Congenital or acquired deficiency of any one of these hormones is uncommon but will result in hypoglycemia, which occurs when endogenous glucose production cannot be mobilized to meet energy needs in the postabsorptive state, that is, 4-6 hr in the newborn and 8-12 hr after meals or during fasting in an infant or child. Concurrent deficiency of several hormones (**hypopituitarism-ACTH-cortisol deficiency combined with GH deficiency**) may result in hypoglycemia that is more severe or appears earlier during fasting than that seen with isolated hormone deficiencies. Most of the causes of hypoglycemia in neonates, infants, and children reflect inappropriate adaptation to fasting as a result of (1) excess insulin action, (2) inadequate counter-regulatory hormone response primarily of cortisol and GH, (3) enzymatic defects in the mechanisms for glycogen storage and release, or (4) defects in gluconeogenesis.

Clinical Manifestations

See Chapter 127 .

Clinical features of hypoglycemia generally fall into 2 categories: (1) symptoms associated with the activation of the autonomic nervous system and epinephrine release, usually seen with a rapid decline in blood glucose concentration and (2) symptoms caused by decreased cerebral glucose utilization (**cerebral glucopenia**), usually associated with a slow decline in blood glucose level or prolonged hypoglycemia (Table 111.1). Although these classic symptoms occur in older children, the symptoms of hypoglycemia in newborns and infants may be subtler and include cyanosis, apnea, hypothermia, hypotonia, poor feeding, lethargy, and seizures, all reflecting the deprivation of glucose for normal brain activity. Some of these symptoms may be so mild that they are missed. Occasionally, hypoglycemia may be asymptomatic in the immediate newborn period. Newborns with hyperinsulinism are often large for gestational age (LGA), mimicking the features of the infant born to a mother with poorly controlled diabetes. Older infants with hyperinsulinism may eat excessively because of chronic hypoglycemia and become obese. In childhood, hypoglycemia may present as behavior problems, inattention, ravenous appetite, or seizures. It may be misdiagnosed as epilepsy, inebriation, personality disorders, headache, hysteria, and developmental delay. A blood glucose determination should always be performed in sick neonates, who should be vigorously treated if concentrations are <55 mg/dL. At any age, hypoglycemia should be considered a cause of an initial episode of convulsions or a sudden deterioration in psychobehavioral functioning or level of consciousness.

Table 111.1

Manifestations of Hypoglycemia in Childhood

Features Associated With Activation of Autonomic Nervous System and Epinephrine Release*

Anxiety [†]
Perspiration [†]
Palpitation (tachycardia) [†]
Pallor [‡]
Tremulousness [‡]
Weakness
Hunger
Nausea
Emesis

Features Associated With Cerebral Glucopenia

Headache [†]
Mental confusion [†]
Visual disturbances (↓ acuity, diplopia) [†]
Organic personality changes [†]
Inability to concentrate [†]
Dysarthria
Staring
Paresthesias
Dizziness
Amnesia
Ataxia, incoordination
Refusal to feed [‡]
Somnolence, lethargy [‡]
Seizures [‡]
Coma
Stroke, hemiplegia, aphasia
Decerebrate or decorticate posture

[*] Some of these features will be attenuated if the patient is receiving β-adrenergic blocking agents.

[†] Common.

[‡] Most common manifestations in the newborn.

Many neonates have asymptomatic (chemical) hypoglycemia. The incidence of symptomatic hypoglycemia is highest in small-for-gestational-age (SGA) infants (Fig. 111.1). The exact incidence of symptomatic hypoglycemia has been difficult to establish because many of the symptoms in neonates occur together with other conditions, such as infections, especially sepsis and meningitis; CNS anomalies, hemorrhage, or edema; hypocalcemia and hypomagnesemia; asphyxia; drug withdrawal; apnea of prematurity; congenital heart disease; or polycythemia.

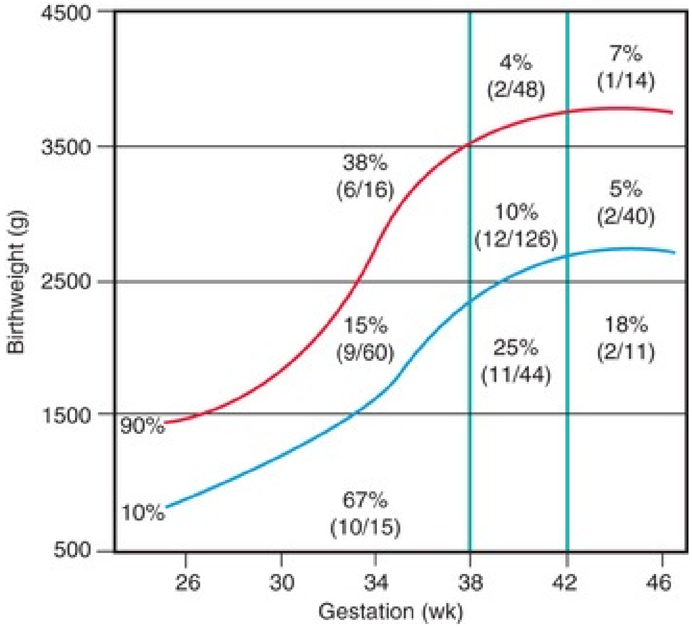

FIG. 111.1 Incidence of hypoglycemia by birthweight, gestational age, and intrauterine growth. (From Lubchenco LO, Bard H: Incidence of hypoglycemia in newborn infants classified by birthweight and gestational age, *Pediatrics* 47:831–838, 1971.)

The onset of symptoms in neonates varies from a few hours to a week after birth. In approximate order of frequency, symptoms include jitteriness or tremors, apathy, episodes of cyanosis, seizures, intermittent apneic spells or tachypnea, weak or high-pitched cry, limpness or lethargy, difficulty feeding (latching on), and eye rolling. Episodes of sweating, sudden pallor, hypothermia, and cardiac arrest and failure may also occur. Frequently, a clustering of episodic symptoms may be noted. Because these clinical manifestations may result from various causes, it is critical to measure serum glucose levels and determine whether symptoms disappear with the administration of sufficient glucose to raise the blood glucose to normal levels; if they do not, other diagnoses must be considered.

Classification of Hypoglycemia in Infants and Children

Classification is based on knowledge of the control of glucose homeostasis in infants and children (Table 111.2).

Table 111.2

Classification of Hypoglycemia in Infants and Children

Neonatal Transitional (Adaptive) Hypoglycemia

Associated With Inadequate Substrate or Immature Enzyme Function in Otherwise Normal Neonates

- Prematurity
- Small for gestational age
- Normal newborn

Transient Neonatal Hyperinsulinism

- Infant of diabetic mother
- Small for gestational age
- Discordant twin
- Birth asphyxia
- Infant of toxemic mother

Neonatal, Infantile, or Childhood Persistent Hypoglycemia

Hyperinsulinism

Recessive K_{ATP} channel HI
Recessive HADH (hydroxyl acyl-CoA dehydrogenase) mutation HI
Recessive UCP2 (mitochondrial uncoupling protein 2) mutation HI
Focal K_{ATP} channel HI
Dominant K_{ATP} channel HI
Atypical congenital hyperinsulinemia (no mutations in *ABCC8* or *KCN11* genes)
Dominant glucokinase HI
Dominant glutamate dehydrogenase HI (hyperinsulinism-hyperammonemia syndrome)
Dominant mutations in HNF-4A and HNF-1A (hepatocyte nuclear factors 4α and 1α) HI with monogenic diabetes of youth later in life
Dominant mutation in SLC16A1 (the pyruvate transporter)—exercise-induced hypoglycemia
Activating mutations in the calcium channel CACNA1D (permit calcium influx and thus unregulated insulin secretion)
Acquired or familial islet adenoma associated with mutations in *MEN1* gene
Beckwith-Wiedemann syndrome
Kabuki syndrome
Insulin administration (Munchausen syndrome by proxy)
Oral sulfonylurea drugs
Congenital disorders of glycosylation

Counter-Regulatory Hormone Deficiency

Panhypopituitarism
Isolated growth hormone deficiency
Adrenocorticotropic hormone deficiency
Addison disease (including congenital adrenal hypoplasia, adrenal leukodystrophy, triple A syndrome, ACTH receptor deficiency, and autoimmune disease complex)
Epinephrine deficiency

Glycogenolysis and Gluconeogenesis Disorders

Glucose-6-phosphatase deficiency (GSD Ia)
Glucose-6-phosphate translocase deficiency (GSD Ib)
Amylo-1,6-glucosidase (debranching enzyme) deficiency (GSD III)
Liver phosphorylase deficiency (GSD VI)
Phosphorylase kinase deficiency (GSD IX)
Glycogen synthetase deficiency (GSD 0)
Fructose-1,6-diphosphatase deficiency
Pyruvate carboxylase deficiency
Galactosemia
Hereditary fructose intolerance

Lipolysis Disorders

Fatty Acid Oxidation Disorders

Carnitine transporter deficiency (primary carnitine deficiency)
Carnitine palmitoyltransferase-1 deficiency
Carnitine translocase deficiency
Carnitine palmitoyltransferase-2 deficiency
Secondary carnitine deficiencies
Very-long-, long-, medium-, short-chain acyl-CoA dehydrogenase deficiency

Other Etiologies

Substrate-Limited Causes

Ketotic hypoglycemia
Poisoning—drugs
Salicylates
Alcohol
Oral hypoglycemic agents
Insulin
Propranolol
Pentamidine
Quinine

Disopyramide
Ackee fruit (unripe)—hypoglycin
Litchi – associated toxin (toxic hypoglycemic syndrome).
Vacor (rat poison)
Trimethoprim-sulfamethoxazole (with renal failure)
L -Asparaginase and other antileukemic drugs

Liver Disease

Reye syndrome
Hepatitis
Cirrhosis
Hepatoma

Amino Acid and Organic Acid Disorders

Maple syrup urine disease
Propionic acidemia
Methylmalonic acidemia
Tyrosinosis
Glutaric aciduria
3-Hydroxy-3-methylglutaric aciduria

Systemic Disorders

Sepsis
Carcinoma/sarcoma (secreting—insulin-like growth factor II)
Heart failure
Malnutrition
Malabsorption
Antiinsulin receptor antibodies
Antiinsulin antibodies
Neonatal hyperviscosity
Renal failure
Diarrhea
Burns

Shock
Chiari malformation
Postsurgical complication
Pseudohypoglycemia (leukocytosis, polycythemia)
Excessive insulin therapy of insulin-dependent diabetes mellitus
Factitious disorder
Nissen fundoplication (dumping syndrome)
Falciparum malaria

GSD, Glycogen storage disease; HI, hyperinsulinemia; K_{ATP} , regulated potassium channel.

Neonatal, Transient, Small-for-Gestational-Age, and Premature Infants

The estimated incidence of symptomatic hypoglycemia in newborns is 1-3 in 1,000 live births. This incidence is increased several fold in certain high-risk neonatal groups (see Table 111.2 and Fig. 111.1). Premature and SGA infants are vulnerable to the development of hypoglycemia. The factors responsible for the high frequency of hypoglycemia in this group, as well as in other groups outlined in Table 111.2 , are related to the inadequate stores of liver glycogen, muscle protein, and body fat needed to sustain the substrates required to meet energy needs. These infants are small by virtue of prematurity or impaired placental transfer of nutrients. Their enzyme systems for gluconeogenesis may not be fully developed. **Transient hyperinsulinism** responsive to diazoxide has also been reported as contributing to hypoglycemia in asphyxiated, SGA, and premature newborn infants. This form of hyperinsulinism, associated with perinatal asphyxia, intrauterine growth restriction, maternal toxemia, and other perinatal stressors, is probably the most common cause of hyperinsulinemic hypoglycemia in neonates and may be quite severe. In most patients the condition resolves quickly, but it may persist to 7 mo of life or longer.

In contrast to deficiency of substrates or enzymes, the hormonal system appears to be functioning normally at birth in most low-risk neonates. Despite hypoglycemia, plasma concentrations of alanine, lactate, and pyruvate are higher, implying their diminished rate of utilization as substrates for gluconeogenesis. Infusion of alanine elicits further glucagon secretion but causes no significant rise in glucose. During the initial 24 hr of life, plasma concentrations of acetoacetate and β-hydroxybutyrate are lower in SGA infants than in full-term infants, implying diminished lipid stores, diminished fatty acid mobilization, impaired ketogenesis, or a combination of these conditions. Diminished lipid stores most likely occur because fat (triglyceride) feeding of newborns results in elevated plasma levels of glucose, ketones such as β-hydroxybutyrate, and FFAs. For infants with perinatal asphyxia and SGA newborns who have transient hyperinsulinism, the combination of hypoglycemia together with diminished concentrations of β-hydroxybutyrate and FFAs are the diagnostic hallmarks of hyperinsulinism.

The role of FFAs and their oxidation in stimulating neonatal gluconeogenesis is essential. The provision of FFAs as triglyceride feedings from formula or human milk together with gluconeogenic precursors may prevent the hypoglycemia that usually ensues after neonatal fasting. For these and other reasons, milk feedings are introduced early (at birth or within 2-4 hr) after delivery. In the hospital setting, when feeding is precluded by virtue of respiratory distress or other illness, or when feedings alone cannot maintain blood glucose concentrations at levels >55 mg/dL, intravenous (IV) glucose at a rate that supplies 4-8 mg/kg/min should be started. Infants with transient neonatal hypoglycemia can usually maintain the blood glucose level spontaneously after 2-3 days of life, but some require longer periods of support. In these latter infants, insulin values >5 µU/mL at the time of hypoglycemia should be treated with diazoxide.

Infants Born to Diabetic Mothers

See Chapter 127.1 .

Of the transient hyperinsulinemic states, infants born to diabetic mothers are the most common. Gestational diabetes affects approximately 2% of pregnant women, and 1 in 1,000 pregnant women have insulin-dependent diabetes. At birth, infants born to these mothers may be large and plethoric, and their body stores of glycogen, protein, and fat are replete.

Hypoglycemia in infants of diabetic mothers is mostly related to hyperinsulinemia and partly related to diminished glucagon secretion. Hypertrophy and hyperplasia of the islets is present, as is a brisk, biphasic, and typically mature insulin response to glucose; this brisk insulin response is absent in normal infants. Infants born to diabetic mothers also have a subnormal surge in plasma glucagon immediately after birth, subnormal glucagon secretion in response to stimuli, and initially, excessive sympathetic activity that may lead to adrenomedullary exhaustion, as reflected by decreased urinary excretion of epinephrine. The normal plasma hormonal pattern of low insulin, high glucagon, and high catecholamines is reversed to a pattern of high insulin, low glucagon, and low epinephrine. As a consequence of this abnormal hormonal profile, endogenous glucose production is significantly inhibited compared with that in normal infants, thus predisposing them to hypoglycemia.

Mothers whose diabetes has been well controlled during pregnancy, labor, and delivery generally have infants near normal size who are less likely to develop neonatal hypoglycemia and other complications formerly considered typical of such infants. In supplying exogenous glucose to these hypoglycemic infants, it is important to avoid hyperglycemia that evokes a prompt exuberant insulin release, which may result in **rebound hypoglycemia** . When needed, glucose should be provided at continuous infusion rates of 4-8 mg/kg/min, but the appropriate dose for each patient must be individually adjusted. During labor and delivery, maternal hyperglycemia should be avoided because it results in fetal hyperglycemia, which predisposes to hypoglycemia when the glucose supply is interrupted at birth. Hypoglycemia persisting beyond day 3 after birth or initially occurring after 1 wk of life requires an evaluation for the causes listed in Table 111.2 .

Infants born with **erythroblastosis fetalis** may also have hyperinsulinemia and share many physical features, such as large body size, with infants born to diabetic mothers. The cause of the hyperinsulinemia in infants with erythroblastosis is not clear.

Persistent or Recurrent Hypoglycemia in Infants and Children

Hyperinsulinism

Most children with hyperinsulinism that causes hypoglycemia present in the neonatal period or later in infancy. Hyperinsulinism is the most common cause of persistent hypoglycemia in early infancy. Infants who have hyperinsulinism may be macrosomic at birth, reflecting the anabolic effects of insulin in utero. There is no history or biochemical evidence of maternal diabetes. The onset of symptoms is from birth to 18 mo of age, but occasionally it only becomes evident in older children.

Insulin concentrations are inappropriately elevated at the time of documented hypoglycemia; with nonhyperinsulinemic hypoglycemia, plasma insulin concentrations should be <5 µU/mL. In affected infants, plasma insulin concentrations at the time of hypoglycemia are usually >5 µU/mL. Some authorities set more stringent criteria, arguing that any value of insulin >2 µU/mL with hypoglycemia is abnormal. The insulin (µU/mL):glucose (mg/dL) ratio is typically >0.4; plasma insulin-like growth factor binding protein-1 (IGFBP-1), β-hydroxybutyrate, and FFA levels are low with hyperinsulinism. Rare instances of activating mutations in the insulin receptor signaling pathway have been reported where the clinical and biochemical features are similar to states of excessive insulin secretion, yet insulin concentrations are low to the point of being undetectable. Therefore, the preferred term is *hyperinsulinism* , to describe a state of increased insulin action. Macrosomic infants may present with hypoglycemia from the 1st days of life. Infants with lesser degrees of hyperinsulinism may manifest hypoglycemia only after the 1st few wk to mo, when the frequency of feedings has been decreased to permit the infant to sleep through the night, and hyperinsulinism prevents the mobilization of endogenous glucose. Increasing appetite and demands for feeding, wilting spells, jitteriness, and frank seizures are the most common presenting features.

Additional clues include the rapid development of fasting hypoglycemia within 4-8 hr of food deprivation, compared with other causes of hypoglycemia (Tables 111.3 and 111.4); the need for high rates of exogenous glucose infusion to prevent hypoglycemia, often at rates >10-15 mg/kg/min; the absence of ketonemia or acidosis; and elevated C-peptide or proinsulin levels at the time of hypoglycemia. The latter insulin-related products are absent in **factitious hypoglycemia** from exogenous administration of insulin as a form of child abuse (see Chapter 16.2). Hypoglycemia is invariably provoked by withholding feedings for several hours, permitting simultaneous measurement of glucose, insulin, ketones, and FFAs in the same sample at the time of clinically manifested hypoglycemia. This is termed the *critical sample.* The glycemic response to glucagon at the time of hypoglycemia reveals a brisk increment in glucose concentration of at least 40 mg/dL, which implies that glucose mobilization has been restrained by insulin but that glycogenolytic mechanisms are intact (Tables 111.5 to 111.7).

Table 111.3

Hypoglycemia in Infants and Children: Clinical and Laboratory Features

GROUP	AGE AT DIAGNOSIS (mo)	GLUCOSE[*] (mg/dL)	INSULIN (μU/mL)	FASTING TIME TO HYPOGLYCEMIA (hr)
Hyperinsulinemia (*N* = 12)				
Mean	7.4	23.1	22.4	2.1 [†]
SEM	2.0	2.7	3.2	0.6
Nonhyperinsulinemia (*N* = 16)				
Mean	41.8	36.1	5.8	18.2
SEM	7.3	2.4	0.9	2.9

[*] In hypoglycemia caused by hyperinsulinism β-hydroxybutyrate and free fatty acids are low compared with normal at same duration of fasting.

[†] Milder forms of hyperinsulinism may require up to 18 hr of fasting to provoke hypoglycemia.

SEM, Standard error of mean.

---

[*] Glucagon 0.5 mg with maximum of 1 mg IV or IM.

[†] Measure once only before or after glucagon administration. Rise in glucose of ≥40 mg/dL after glucagon given at the time of hypoglycemia strongly suggests a hyperinsulinemic state with adequate hepatic glycogen stores and intact glycogenolytic enzymes. If ammonia is elevated to 100-200 µM, consider activating mutation of glutamate dehydrogenase.

Table 111.6

Criteria for Diagnosing Hyperinsulinism Based on "Critical" Samples (Drawn at a Time of Fasting Hypoglycemia: Plasma Glucose <50 mg/dL)

1. Hyperinsulinemia (plasma insulin >2 µU/mL)*
2. Hypofatty acidemia (plasma free fatty acids <1.5 mmol/L)
3. Hypoketonemia (plasma β-hydroxybutyrate <2.0 mmol/L)
4. Inappropriate glycemic response to glucagon, 1 mg IV (change in glucose >40 mg/dL)

---

[*] Depends on sensitivity of insulin assay.

Table 111.7

Diagnosis of Acute Hypoglycemia in Infants and Children

Acute Symptoms Present

1. Obtain blood sample before and 30 min after glucagon administration.
2. Obtain urine as soon as possible. Examine for ketones; if not present and hypoglycemia confirmed, suspect hyperinsulinemia or fatty acid oxidation defect; if present, suspect ketotic, hormone deficiency, inborn error of glycogen metabolism, or defective gluconeogenesis.
3. Measure glucose in the original blood sample. If hypoglycemia is confirmed, proceed with substrate-hormone measurement as in Table 111.5 .
4. If glycemic increment after glucagon exceeds 40 mg/dL above basal, suspect hyperinsulinemia.
5. If insulin level at time of confirmed hypoglycemia is >5 µU/mL, suspect endogenous hyperinsulinemia; if >100 µU/mL, suspect factitious hyperinsulinemia (exogenous insulin injection). Admit to hospital for supervised fast.
6. If cortisol is <10 µg/dL or growth hormone is <5 ng/mL, or both, suspect adrenal insufficiency or pituitary disease, or both. Admit to hospital for hormonal testing and neuroimaging.

History Suggestive: Acute Symptoms Not Present

1. Careful history for relation of symptoms to time and type of food intake, considering age of patient. Exclude possibility of alcohol or drug ingestion. Assess possibility of insulin injection, salt craving, growth velocity, or intracranial pathology.
2. Careful examination for hepatomegaly (glycogen storage disease; defect in gluconeogenesis); pigmentation (adrenal failure); stature and neurologic status (pituitary disease).
3. Admit to hospital for provocative testing:
    a. 24 hr fast under careful observation; when symptoms provoked, proceed with steps 1-4 as when acute symptoms present.
    b. Pituitary-adrenal function using arginine-insulin stimulation test if indicated.
4. Consider molecular diagnostic test before liver biopsy for histologic and enzyme determinations.

5. Oral glucose tolerance test (1.75 g/kg; max 75 g) if reactive hypoglycemia suspected (e.g., dumping syndrome).

The measurement of serum IGFBP-1 concentration may help diagnose hyperinsulinism. The secretion of IGFBP-1 is acutely inhibited by insulin action; IGFBP-1 concentrations are low during hyperinsulinism-induced hypoglycemia. In patients with spontaneous or fasting-induced hypoglycemia with a low insulin level (ketotic hypoglycemia, normal fasting), IGFBP-1 concentrations are significantly higher.

The differential diagnosis of endogenous hyperinsulinism includes **diffuse β-cell hyperplasia** or **focal β-cell microadenoma** . The distinction between these 2 major entities is important because the diffuse hyperplasia, if unresponsive to medical therapy, requires near-total pancreatectomy, despite which hypoglycemia may persist or diabetes mellitus may ensue later. Some, but not all, affected infants may respond to sirolimus. By contrast, focal adenomas diagnosed preoperatively or intraoperatively permit localized curative resection with subsequent normal glucose metabolism. Approximately 50% of the autosomal recessive or sporadic forms of neonatal/infantile hyperinsulinism are caused by focal microadenomas, which may be distinguished from the diffuse form by the pattern of insulin response to selective insulin secretagogues infused into an arterial branch supplying the pancreas, with sampling by the hepatic vein. However, these invasive and technically difficult procedures have been largely abandoned in favor of positron emission tomography (PET) using 18-fluoro-L -dopa. This technique can distinguish the diffuse form (uniform fluorescence throughout the pancreas) from the focal form (focal uptake of 18-fluoro-L -dopa and localized fluorescence) with an extremely high degree of reliability, success, specificity, and sensitivity (see Fig. 111.3).

Insulin-secreting **macroadenomas** are rare in childhood and may be diagnosed preoperatively by CT or MRI. The plasma levels of insulin alone, however, cannot distinguish the aforementioned entities. The diffuse or microadenomatous forms of islet cell hyperplasia represent a variety of genetic defects responsible for abnormalities in the endocrine pancreas, characterized by autonomous insulin secretion that is not appropriately reduced when blood glucose declines spontaneously or in response to provocative maneuvers such as fasting (see Tables 111.4 , 111.7 , and 111.8). Clinical, biochemical, and molecular genetic approaches permit classification of congenital hyperinsulinism, formerly termed *nesidioblastosis,* into distinct entities.

Persistent hyperinsulinemic hypoglycemia of infancy (PHHI) may be inherited or sporadic, is severe, and is caused by mutations that affect the regulation of the potassium channel intimately involved in insulin secretion by the pancreatic β cell (Fig. 111.2). Normally, glucose entry into the β cell is enabled by the non–insulin-responsive glucose transporter GLUT-2. On entry, glucose is phosphorylated to glucose-6-phosphate by the enzyme glucokinase, enabling glucose metabolism to generate ATP. The rise in the molar ratio of ATP relative to adenosine diphosphate (ADP) closes the ATP-sensitive potassium channel in the cell membrane (K_{ATP} channel). This channel is composed of 2 subunits, the K_{IR} 6.2 channel, part of the family of inward-rectifier potassium channels, and a regulatory component in intimate association with K_{IR} 6.2 known as the *sulfonylurea receptor* (SUR1). Together, K_{IR} 6.2 and SUR1 constitute the potassium-sensitive ATP channel K_{ATP} . Normally, the K_{ATP} is open, but with the rise in ATP and closure of the channel, potassium accumulates intracellularly, causing depolarization of the membrane, opening of voltage-gated calcium channels, influx of calcium into the cytoplasm, and secretion of insulin by exocytosis. The genes for both SUR1 and K_{IR} 6.2 are located close together on the short arm of chromosome 11, the site of the insulin gene.

FIG. 111.2 **Schematic of the pancreatic cell with some important steps in insulin secretion. The membrane-spanning, adenosine triphosphate (ATP)–sensitive potassium**

(K^+) channel (K_{ATP}) consists of 2 subunits: the sulfonylurea receptor (SUR) and the inward rectifying K channel (K_{IR} 6.2). In the resting state, the ratio of ATP to adenosine diphosphate (ADP) maintains K_{ATP} in an open state, permitting efflux of intracellular K^+. When blood glucose concentration rises, its entry into the β cell is facilitated by the Glut-2 glucose transporter, a process not regulated by insulin. Within the β cell, glucose is converted to glucose-6-phosphate by the enzyme glucokinase and then undergoes metabolism to generate energy. The resultant increase in ATP relative to ADP closes K_{ATP}, preventing efflux of K^+, and the rise of intracellular K^+ depolarizes the cell membrane and opens a calcium (Ca^{2+}) channel. The intracellular rise in Ca^{2+} triggers insulin secretion via exocytosis. Sulfonylureas trigger insulin secretion by reacting with their receptor (SUR) to close K_{ATP}; diazoxide inhibits this process, whereas somatostatin, or its analog octreotide, inhibits insulin secretion by interfering with calcium influx. Genetic mutations in SUR1 or K_{IR} 6.2 that prevent K_{ATP} from being open tonically maintain inappropriate insulin secretion and are responsible for autosomal recessive forms of persistent hyperinsulinemic hypoglycemia of infancy (PHHI). One form of autosomal dominant PHHI is caused by an activating mutation in glucokinase. The amino acid leucine also triggers insulin secretion by closure of K_{ATP}. Metabolism of leucine is facilitated by the enzyme glutamate dehydrogenase (GDH), and overactivity of this enzyme in the pancreas leads to hyperinsulinemia with hypoglycemia, associated with hyperammonemia from overactivity of GDH in the liver. Mutations in the pyruvate channel SLC16A1 can cause ectopic expression in the β cell and permit pyruvate, accumulated during exercise, to induce insulin secretion and thus exercise-induced hypoglycemia. Mutations in the mitochondrial uncoupling protein 2 (UCP2) and hydroxyl acyl-CoA dehydrogenase (HADH) are associated with hyperinsulinism (HI) by mechanisms yet to be defined. Mutations in the transcription factors hepatocyte nuclear factors (HNF) 4α and 1α can be associated with neonatal macrosomia and HI, but progress to monogenic diabetes of youth (MODY) later in life. Activating mutations in the calcium channel CACNA1D permit calcium influx and hence unregulated insulin secretion at membrane voltages which normally exclude calcium flux. √, Stimulation; GTP, guanosine triphosphate; X, inhibition.

Inactivating mutations in the gene for SUR1 or, less often, K_{IR} 6.2 prevent the potassium channel from opening; it remains variably closed with constant depolarization and therefore constant inward flux of calcium. Thus, insulin secretion is continuous and not governed by the glucose concentration. A milder autosomal dominant form of these defects is also reported. Similarly, an **activating** mutation in the gene for glucokinase or for glutamate dehydrogenase enzyme activity increases substrate metabolism and results in closure of the potassium channel through overproduction of ATP, which causes hyperinsulinism. Genetic defects in fatty acid metabolism, in the insulin transcription factors HNF-4α and HNF-1α, and in the uncoupling protein UCP-2 of the mitochondrial gene complex also have been involved in hyperinsulinemic hypoglycemia. Most recently, an activating mutation in the calcium channel has been reported to permit flux of calcium into the β cell, resulting in excessive, dysregulated insulin secretion and hypoglycemia that responds to diazoxide. **Inactivating** mutations of the glucokinase gene or **activating** mutations of the ATP-regulated potassium channel, which prevent or limit closure of the channel, are responsible for inadequate insulin secretion and form the basis of some forms of maturity-onset diabetes of youth and neonatal diabetes mellitus (see Chapter

607).

The familial forms of PHHI are more common in certain populations, notably Arabic and Ashkenazi Jewish communities, where it may reach an incidence of approximately 1 in 2,500, compared with the sporadic rates in the general population of 1 in 50,000. These **autosomal recessive forms** of PHHI typically present in the immediate newborn period as macrosomic newborns with a weight frequently >4.0 kg and severe recurrent or persistent hypoglycemia manifesting in the initial hours or days of life. Glucose infusions as high as 15-20 mg/kg/min and frequent feedings fail to maintain euglycemia. **Diazoxide** , which acts by opening K_{ATP} channels, fails to control hypoglycemia adequately. Somatostatin (**octreotide**), which also opens K_{ATP} channels and inhibits calcium flux, may be partially effective in 50% of patients (see Fig. 111.2). Calcium channel–blocking agents have had inconsistent effects. When affected patients are unresponsive to these measures, **pancreatectomy** is strongly recommended to avoid the long-term neurologic sequelae of hypoglycemia. If surgery is undertaken, preoperative CT or MRI rarely reveals an isolated adenoma, which would then permit local resection. Intraoperative ultrasonography may identify a small impalpable adenoma, permitting local resection. Adenomas often present in late infancy or early childhood.

Distinguishing between **focal** and **diffuse** cases of **persistent hyperinsulinism** has been attempted in several ways. Preoperatively, transhepatic portal vein catheterization and selective pancreatic venous sampling to measure insulin may localize a focal lesion from the step-up in insulin concentration at a specific site. Selective catheterization of arterial branches supplying the pancreas, followed by infusion of a secretagogue such as calcium and portal vein sampling for insulin concentration (arterial stimulation–venous sampling) may localize a lesion. Both approaches are highly invasive, restricted to specialized centers, and not uniformly successful in distinguishing the focal from the diffuse forms. Thus these techniques are not recommended and have largely been abandoned. Fluorine 18 (^{18} F)–labeled L -dopa combined with PET scanning is a highly promising means to distinguish the focal from the diffuse lesions of hyperinsulinism unresponsive to medical management (Fig. 111.3). The gold standard remains intraoperative **histologic** characterization. Diffuse hyperinsulinism is characterized by large β cells with abnormally large nuclei, whereas focal adenomatous lesions display small and normal β-cell nuclei. Although *SUR1* mutations are present in both types, the focal lesions arise by a random loss of a maternally imprinted growth-inhibitory gene on maternal chromosome 11p, in association with paternal transmission of a mutated *SUR1* or K_{IR} 6.2 paternal chromosome 11p, expressing the insulin-like growth factor 2 *(IGF2)* gene. Thus the focal form represents a double hit–loss of maternal repressor and transmission of a paternal mutation that contains a growth-promoting gene. This is similar to what occurs in children with the hyperinsulinemic hypoglycemia seen in Beckwith-Wiedemann syndrome, as discussed later.

A, Diffuse uptake of ^{18}F-L -dopa is visualized throughout the pancreas. Transverse views show B, normal pancreatic tissue on abdominal CT; C, diffuse uptake of ^{18}F-L -dopa in pancreas; and D, confirmation of pancreatic uptake of ^{18}F-L -dopa with co-registration. H, Head of pancreas; T, tail of pancreas. II Panels (*focal*): ^{18}F-L -dopa PET of patient with focal form of congenital hyperinsulinism. A, Discrete area of increased ^{18}F-L -dopa uptake is visualized in the head of the pancreas. The intensity of this area is greater than that observed in the liver and neighboring normal pancreatic tissue. Transverse views show B, normal pancreatic tissue on abdominal CT; C, focal uptake of ^{18}F-L -dopa in pancreatic head; and D, confirmation of ^{18}F-L -dopa uptake in the pancreatic head with co-registration. (Courtesy of Dr. Olga Hardy, Children's Hospital of Philadelphia.)

Local excision of the focal adenomatous islet cell hyperplasia results in a cure with little or no recurrence. For the diffuse form, near-total resection of 85–90% of the pancreas is recommended. The near-total pancreatectomy required for the diffuse hyperplastic lesions, however, is often associated with persistent hypoglycemia or later development of hyperglycemia or frank, insulin-dependent diabetes mellitus.

Further resection of the remaining pancreas may occasionally be necessary if hypoglycemia recurs and cannot be controlled by medical measures, such as the use of octreotide or diazoxide.

Experienced pediatric surgeons in medical centers equipped to provide the necessary preoperative and postoperative care, diagnostic evaluation, and management should perform surgery. In some patients who have been managed medically, hyperinsulinism and hypoglycemia regress over months. If hypoglycemia first manifests between 3 and 6 mo of age or later, a therapeutic trial using medical approaches with diazoxide, octreotide, and frequent feedings can be attempted for up to 2-4 wk. Failure to maintain euglycemia without undesirable side effects from the drugs may prompt the need for surgery. Some success in suppressing insulin release and correcting hypoglycemia in patients with PHHI has been reported with the use of the long-acting somatostatin analog octreotide. Most cases of neonatal PHHI are sporadic; familial forms permit genetic counseling on the basis of anticipated autosomal recessive inheritance.

A 2nd form of familial PHHI suggests **autosomal dominant inheritance** . The clinical features tend to be less severe, and onset of hypoglycemia is most likely, but not exclusively, to occur beyond the immediate newborn period and usually beyond the period of weaning, at an average age at onset of 1 yr. At birth, macrosomia is rarely observed, and response to diazoxide is almost uniform. The initial presentation may be delayed and rarely may occur as late as 30 yr, unless provoked by fasting. The genetic basis for this autosomal dominant form has not been delineated; it is not always linked to K_{IR} 6.2/*SUR1*. The activating mutation in glucokinase is transmitted in an autosomal dominant manner. If a family history is present, genetic counseling for a 50% recurrence rate can be given for future offspring.

A 3rd form of persistent PHHI is associated with mild and asymptomatic **hyperammonemia** , usually as a sporadic occurrence, although dominant inheritance occurs. Presentation is more like the autosomal dominant form than the autosomal recessive form. Diet and diazoxide control symptoms, but pancreatectomy may be necessary in some patients. The association of hyperinsulinism and hyperammonemia is caused by an inherited or de novo gain-of-function mutation in the enzyme glutamate dehydrogenase. The resulting increase in glutamate oxidation in the pancreatic β cell raises the ATP concentration and thus the ATP/ADP ratio, which closes K_{ATP} , leading to membrane depolarization, calcium influx, and insulin secretion (see Fig. 111.2). In the liver the excessive oxidation of glutamate to β-ketoglutarate may generate ammonia and divert glutamate from being processed to *N* -acetylglutamate, an essential cofactor for removal of ammonia through the urea cycle by activation of the enzyme carbamoyl phosphate synthetase. The hyperammonemia is mild, with concentrations of 100-200 µM/L, and produces no CNS symptoms or consequences, as seen in other hyperammonemic states. Leucine, a potent amino acid for stimulating insulin secretion and implicated in **leucine-sensitive hypoglycemia** , acts by allosterically stimulating glutamate dehydrogenase. Thus, leucine-sensitive hypoglycemia may be a form of the hyperinsulinemia-hyperammonemia syndrome or a potentiation of mild disorders of the K_{ATP} channel; it need not always be associated with a modest increase in serum ammonia.

Hypoglycemia associated with hyperinsulinemia is also seen in approximately 50% of patients with **Beckwith-Wiedemann syndrome** (see Chapter 576). This syndrome is caused by an imprinting disorder (see Chapter 98.8) and characterized by omphalocele, gigantism, macroglossia, microcephaly, and visceromegaly (Fig. 111.4). Distinctive lateral earlobe fissures and facial nevus flammeus are present; hemihypertrophy occurs in many of these infants. Diffuse islet cell hyperplasia occurs in infants with hypoglycemia. The diagnostic and therapeutic approaches are the same as those discussed previously, although microcephaly and slowing of brain development may occur independent of hypoglycemia. Patients with Beckwith-Wiedemann syndrome may acquire tumors, including Wilms tumor, hepatoblastoma, adrenal carcinoma, gonadoblastoma, and rhabdomyosarcoma. This overgrowth syndrome is caused by mutations in the chromosome 11p15.5 region close to the genes for insulin, *SUR1*, K_{IR} 6.2, and *IGF2.* Duplications in this region and genetic imprinting from a defective or absent copy of the maternally derived gene are involved in the variable features and patterns of transmission. Hypoglycemia may resolve in weeks to months of medical therapy. Pancreatic resection may rarely be needed.

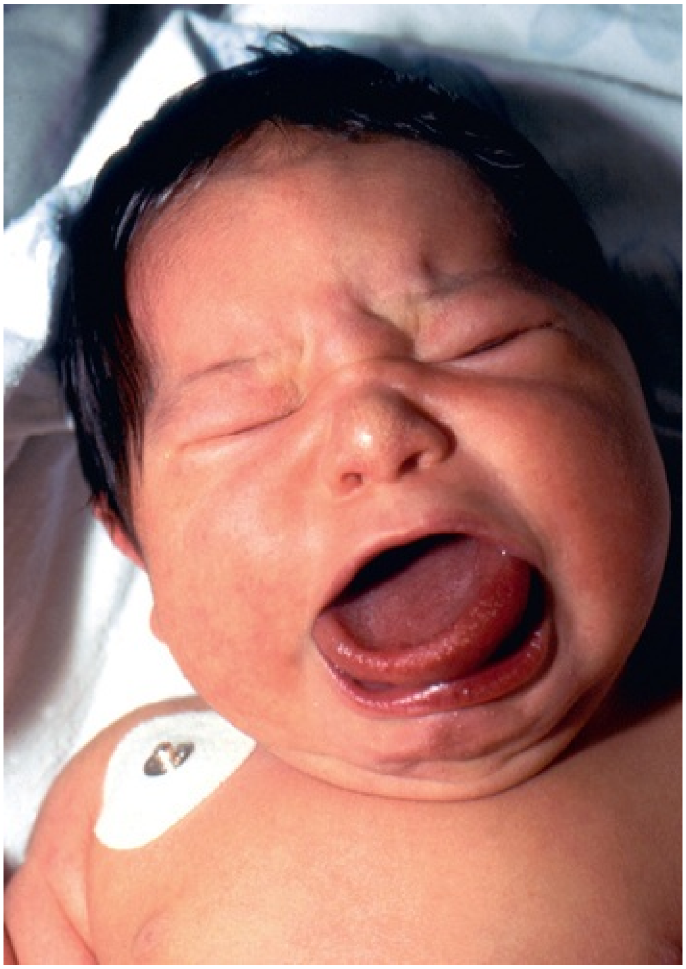

FIG. 111.4 Beckwith-Wiedemann syndrome. (Courtesy of Dr. Michael Cohen, Dalhousie University, Halifax, Nova Scotia. From Jones KL: *Smith's recognizable patterns of human malformation* , ed 6, Philadelphia, 2006, Saunders.)

Kabuki syndrome , caused by mutations in a methyltransferase or demethylase, is the 2nd most common syndromic form of hyperinsulinemic hypoglycemia of infancy (HHI) after Beckwith-Wiedemann Syndrome. Neonatal hypoglycemia with congenital hyperinsulinism occurs in about 70% of children with this syndrome; most are diazoxide responsive. Congenital hyperinsulinemia also is reported to occur in **Turner syndrome** . Activating mutations in *AKT2* and in PI3-kinase of the insulin signaling cascade have been reported in association with hypoketotic hypoglycemia and other metabolic features indicative of excessive insulin action, but insulin concentrations are subnormal as a result of negative feedback from the activated insulin receptor signal.

HHI is reported as a manifestation of 1 form of **congenital disorder of glycosylation** . Disorders of protein glycosylation usually present with neurologic symptoms but may also include liver dysfunction with hepatomegaly, intractable diarrhea, protein-losing enteropathy, and hypoglycemia (see Chapter 105.6). These disorders are often underdiagnosed. One entity associated with HHI is caused by phosphomannose isomerase deficiency, and clinical improvement followed supplemental treatment with oral mannose, 0.17 g/kg 6 times per day.

After the 1st 12 mo of life, hyperinsulinemic states are uncommon until islet cell adenomas reappear as a cause after the patient is several years of age. Hyperinsulinemia as a result of **islet cell adenoma** should be considered in any child ≥5 yr who presents with hypoglycemia. Islet cell adenomas do not “light up” during scanning with ^{18}F-labeled L -dopa. An islet cell adenoma in a child should arouse suspicion of the possibility of **multiple endocrine neoplasia type I** (Wermer syndrome), which involves mutations in the menin gene and may be associated with hyperparathyroidism and pituitary tumors. Tables 111.7 and 111.8 outline the diagnostic approach. In a newborn, fasting for only 6-8 hr (1 missed meal in a 3-4 hr feeding schedule) may be sufficient to provoke hypoglycemia, and this maneuver should be performed to exclude persistent forms of hypoglycemia before discharge from a neonatal unit. In older infants and children, fasting for up to 24-36 hr usually provokes hypoglycemia; coexisting hyperinsulinemia confirms the diagnosis, provided that factitious administration of insulin by the parents is excluded. Occasionally, provocative tests may be required. Exogenously administered insulin can be distinguished from endogenous insulin by simultaneous measurement of C-peptide concentration. If C-peptide levels are elevated, endogenous insulin secretion is responsible for the hypoglycemia; if C-peptide levels are low but insulin values are high, exogenous insulin has been administered, perhaps as a form of child abuse (see Chapter 16.2). Islet cell adenomas at this age are treated by surgical excision. Antibodies to insulin or the insulin receptor (**insulin mimetic action**) are also rarely associated with hypoglycemia. Some **tumors** produce IGFs, thereby provoking hypoglycemia by interacting with the insulin receptor. The astute clinician must also consider the possibility of deliberate or accidental ingestion of drugs such as a sulfonylurea or related compound that stimulates insulin secretion. In such cases, both insulin and C-peptide concentrations in blood will be elevated. Inadvertent substitution of an insulin secretagogue by a dispensing error should be considered in those taking medications who suddenly develop documented hypoglycemia.

[1] Glucose-6-phosphatase deficiency.

[2] Hepatomegaly may not be present in the newborn.

Details of each condition are discussed in the text.

0 absence of ketonuria or hepatomegaly; + mildly detected ketonuria or hepatomegaly; ++ moderately increased; +++ markedly increased; 0, Absence; ↑ or ↓ indicates, respectively, small increase or decrease; ↑↑ or ↓↓ indicates, respectively, large increase or decrease.

A rare form of hyperinsulinemic hypoglycemia has been reported after exercise. Whereas glucose and insulin remain unchanged in most people after moderate, short-term exercise, rare patients manifest severe hypoglycemia with hyperinsulinemia 15-50 min after the same standardized exercise. This form of **exercise-induced hyperinsulinism** is caused by abnormal responsiveness of β-cell insulin release to pyruvate generated during exercise. The gene responsible for this syndrome, *SLC16A1*, regulates a transporter (MCT1R) that controls the entry of pyruvate into cells. Dominant mutations in *SLC16A1* that increase the ectopic expression of MCTR1 in pancreatic β cells permit excessive entry of pyruvate into β cells and act to increase insulin secretion, with resultant hypoglycemia during exercise.

Hypoglycemia with so-called nesidioblastosis has also rarely been reported after **bariatric surgery** for obesity. The mechanism for this form of hyperinsulinemic hypoglycemia remains to be defined.

Infants and children with **Nissen fundoplication** , a relatively common procedure used to ameliorate gastroesophageal reflux, frequently have an associated "dumping" syndrome with hypoglycemia. Characteristic features include significant hyperglycemia of 200 mg/dL and up to 500 mg/dL 30 min postprandially, and severe hypoglycemia (average 32 mg/dL in one series) 1.5-3.0 hr later. The early hyperglycemia phase is associated with brisk and excessive insulin release that causes the rebound hypoglycemia. A role for exaggerated GLP1 secretion has been proposed and glucagon responses have been reported to be inappropriately low in some cases. However, the physiologic mechanisms are not always clearly understood, and attempted treatments not always effective; **acarbose** , an inhibitor of glucose absorption, was reported to be successful in one small series.

Endocrine Deficiencies

Hypoglycemia associated with endocrine deficiency is usually caused by adrenal cortisol insufficiency with or without associated growth hormone deficiency (see Chapters 573 and 593). In **panhypopituitarism** , isolated adrenocorticotropic hormone (ACTH) or GH deficiency, or combined ACTH and GH deficiency, the incidence of hypoglycemia is as high as 20%. In the newborn period, hypoglycemia may be the presenting feature of hypopituitarism; in males, a microphallus may provide a clue to a coexisting deficiency of gonadotropin. Newborns with hypopituitarism often have a form of hepatitis associated with **cholestatic jaundice** and hypoglycemia. The combination of hypoglycemia and cholestatic jaundice requires exclusion of hypopituitarism as a cause, as the jaundice resolves with replacement treatment of GH, cortisol, and thyroid as required. This constellation is often associated with the syndrome of **septooptic dysplasia.** When adrenal disease is severe, as in congenital adrenal hyperplasia caused by enzyme defects in cortisol synthesis, adrenal hemorrhage, or congenital adrenal hypoplasia, serum electrolyte disturbances with hyponatremia and hyperkalemia or disordered genital development may provide diagnostic clues (see Chapter 576). In older children, failure of growth should suggest GH deficiency. Hyperpigmentation, weakness, or salt craving may provide the clue to primary adrenal insufficiency (**Addison disease**), characterized by greatly increased ACTH levels or adrenal unresponsiveness to exogenous ACTH caused by a defect in the adrenal receptor for ACTH, congenital adrenal hypoplasia, adrenoleukodystrophy, or the Allgrove triple A syndrome. The frequent association of Addison disease in childhood with hypoparathyroidism (hypocalcemia), chronic mucocutaneous candidiasis, and other endocrinopathies that constitute the autoimmune polyendocrinopathy syndrome type 1 should be considered. Adrenoleukodystrophy and congenital adrenal hypoplasia are sex-linked conditions and should be considered in the differential diagnosis of primary Addison disease in male children (see Chapter 104.2).

Hypoglycemia in cortisol-GH deficiency may be caused by decreased gluconeogenic enzymes with cortisol deficiency, increased glucose utilization because of a lack of the antagonistic effects of GH on insulin action, or failure to supply endogenous gluconeogenic substrate in the form of alanine and lactate with compensatory breakdown of fat and generation of ketones. Deficiency of these hormones results in reduced gluconeogenic substrate, which resembles the syndrome of ketotic hypoglycemia. Investigation of a child with hypoglycemia therefore requires exclusion of ACTH-cortisol or GH deficiency and, if diagnosed, its appropriate replacement with cortisol or GH.

Epinephrine deficiency could theoretically be responsible for hypoglycemia. Urinary excretion of epinephrine has been decreased in some patients with spontaneous or insulin-induced hypoglycemia in whom absence of pallor and tachycardia were also noted. This suggests that failure of catecholamine release, as the result of a defect anywhere along the hypothalamic-autonomic-adrenomedullary axis, might be responsible for the hypoglycemia. This possibility has been challenged, however, because of the rarity of hypoglycemia in patients with bilateral adrenalectomy, provided that they receive adequate glucocorticoid replacement, and because diminished epinephrine excretion is found in normal patients with repeated insulin-induced hypoglycemia. Many of the patients described as having hypoglycemia with failure of epinephrine excretion fit the criteria for ketotic hypoglycemia (see next). Also, repetitive hypoglycemia leads to diminished cortisol plus epinephrine responses, as seen most often in insulin-treated diabetes mellitus and the syndrome of hypoglycemia unawareness, associated with autonomic failure.

Glucagon deficiency in infants or children may theoretically be associated with hypoglycemia but has never been documented.

Substrate-Limited Etiologies

Ketotic Hypoglycemia

Idiopathic ketotic hypoglycemia is the most common form of *childhood* hypoglycemia. This condition usually presents between ages 18 mo and 5 yr and remits spontaneously by 8-9 yr. Hypoglycemic episodes typically occur during periods of intercurrent illness when food intake is limited. The classic history is of a child who eats poorly or completely avoids the evening meal, is difficult to arouse from sleep the following morning and thus eats poorly again, and may have a seizure or may be comatose by mid-morning. Another common presentation occurs when parents sleep late, and the affected child is unable to eat breakfast, thus prolonging the overnight fast.

At the time of documented hypoglycemia, there is associated marked ketonuria and ketonemia; plasma insulin concentrations are appropriately low, ≤5 µU/mL, thus excluding hyperinsulinemia. A ketogenic-provocative diet, formerly a diagnostic test, is no longer used to establish the diagnosis because fasting alone provokes a hypoglycemic episode with ketonemia and ketonuria within 12-18 hr in susceptible individuals. Normal children of similar age can withstand fasting without hypoglycemia developing during the same period, although even normal children may acquire these features by 36 hr of fasting.

Children with ketotic hypoglycemia have plasma alanine concentrations that are markedly reduced in the basal state after an overnight fast and decline even further with prolonged fasting. **Alanine** , produced in muscle, is a major gluconeogenic precursor. Alanine is the only amino acid that is significantly lower in these children, and infusions of alanine (250 mg/kg) produce a rapid rise in plasma glucose without causing significant changes in blood lactate or pyruvate levels, indicating that the entire gluconeogenic pathway from the level of pyruvate is intact, but that there is a deficiency of substrate. Glycogenolytic pathways are also intact because glucagon induces a normal glycemic response in affected children in the fed state. The levels of hormones that counter hypoglycemia are appropriately elevated, and insulin is appropriately low.

The etiology of ketotic hypoglycemia may be a defect in any of the complex steps involved in protein catabolism, oxidative deamination of amino acids, transamination, alanine synthesis, or alanine efflux from muscle. Children with ketotic hypoglycemia are frequently smaller than age-matched controls and often have a history of transient neonatal hypoglycemia. Any decrease in muscle mass may compromise the supply of gluconeogenic substrate at a time when glucose demands per unit of body weight are already relatively high, thus predisposing the patient to the rapid development of hypoglycemia, with ketosis representing the attempt to switch to an alternative fuel supply. Children with ketotic hypoglycemia may represent the low end of the spectrum of children's capacity to tolerate fasting. Similar relative intolerance to fasting is present in normal children, who cannot maintain blood glucose after 30-36 hr of fasting, compared with the adult's capacity for prolonged fasting. Although the defect may be present at birth, it may not be evident until the child is stressed by more prolonged periods of calorie restriction. Moreover, the spontaneous remission observed in children at age 8-9 yr might be explained by the increase in muscle bulk with its resultant increase in supply of endogenous substrate and the relative decrease in glucose requirement per unit of body mass with increasing age.

In anticipation of spontaneous resolution of this syndrome, **treatment** of ketotic hypoglycemia consists of frequent feedings of a high-protein, high-carbohydrate diet. During intercurrent illnesses, parents should be taught to test the child's urine for the presence of ketones, the appearance of which precedes hypoglycemia by several hours. In the presence of ketonuria, liquids of high carbohydrate content should be offered to the child. If these cannot be tolerated, the child should be treated with IV glucose administration in a hospital.

Branched-Chain Ketonuria (Maple Syrup Urine Disease)

See Chapter 103.6 .

The hypoglycemic episodes were once attributed to high levels of leucine, but evidence indicates that interference with the production of alanine and its availability as a gluconeogenic substrate during calorie deprivation is responsible for hypoglycemia.

Glycogen Storage Disease

See Chapter 105.1 .

Glucose-6-Phosphatase Deficiency (Type I Glycogen Storage Disease)

Affected children usually display a remarkable tolerance to their chronic hypoglycemia; blood glucose values in the range of 20-50 mg/dL are not associated with the classic symptoms of hypoglycemia, possibly reflecting the adaptation of the CNS to ketone bodies and lactate as alternative fuels. Hepatomegaly and poor growth are consistent physical features. Hypoglycemia is associated with acidosis (HCO_3^- <18 mEq/L) and increased β-hydroxybutyrate and lactate; hyperuricemia also is frequently seen. Management is discussed in detail in Chapter 105.1 .

Amylo-1,6-Glucosidase Deficiency (Debrancher Enzyme Deficiency; Type III Glycogen Storage Disease)

See Chapter 105.1 .

Liver Phosphorylase Deficiency (Type VI Glycogen Storage Disease)

Low hepatic phosphorylase activity may result from a defect in any of the steps of activation; a variety of defects have been described. Hepatomegaly, excessive deposition of glycogen in liver, growth retardation, and occasional symptomatic hypoglycemia occur. A diet high in protein and reduced in carbohydrate usually prevents hypoglycemia.

Glycogen Synthetase Deficiency

The inability to synthesize glycogen is rare. Hypoglycemia and hyperketonemia occur after fasting because glycogen reserves are greatly decreased or absent. After feeding, however, hyperglycemia with glucosuria may occur because of the inability to assimilate some of the glucose load into glycogen. During fasting hypoglycemia, levels of the counter-regulatory hormones, including catecholamines, are appropriately elevated or normal, and insulin levels are appropriately low. The liver is not enlarged. Protein-rich feedings at frequent intervals result in dramatic clinical improvement, including growth velocity. Glycogen synthetase deficiency mimics the syndrome of **ketotic hypoglycemia** and should be considered in the differential diagnosis of that syndrome.

Disorders of Gluconeogenesis

Fructose-1,6-Diphosphatase Deficiency

See Chapter 105.3 .

A deficiency of this enzyme results in a block of gluconeogenesis from all possible precursors below the level of fructose-1,6-diphosphate. Infusion of these gluconeogenic precursors results in lactic acidosis without a rise in glucose; acute hypoglycemia may be provoked by inhibition of glycogenolysis. Glycogenolysis remains intact, and glucagon elicits a normal glycemic response in the fed, but not in the fasted, state. Accordingly, affected individuals have hypoglycemia only during caloric deprivation, as in fasting, or during intercurrent illness. As long as glycogen stores remain normal, hypoglycemia does not develop. In affected families, there may be a history of siblings with known hepatomegaly who died in infancy with unexplained metabolic acidosis.

Defects in Fatty Acid Oxidation

See Chapter 104.1 .

The important role of fatty acid oxidation in maintaining gluconeogenesis is underscored by examples of congenital or drug-induced defects in fatty acid metabolism that may be associated with fasting hypoglycemia.

Various congenital enzymatic deficiencies cause defective carnitine or fatty acid metabolism. A severe and relatively common form of fasting hypoglycemia with hepatomegaly, cardiomyopathy, and hypotonia occurs with long- and medium-chain fatty acid CoA dehydrogenase deficiency. Plasma carnitine levels are low, ketones are not present, but dicarboxylic aciduria is present in urine. Clinically, patients with **acyl-CoA dehydrogenase deficiency** present with a Reye-like syndrome (see Chapter 388), recurrent episodes of severe fasting hypoglycemic coma, and cardiorespiratory arrest (sudden infant death syndrome–like events). Severe hypoglycemia and metabolic acidosis without ketosis also occur in patients with multiple acyl-CoA dehydrogenase disorders. Hypotonia, seizures, and acrid odor are other clinical clues. Survival depends on whether the defects are severe or mild; diagnosis is established from studies of enzyme activity in liver biopsy tissue or in cultured fibroblasts from affected patients. Tandem mass spectrometry can be employed for blood samples, even those on filter paper, for screening of congenital inborn errors. Molecular diagnosis also is available for most entities. The frequency of acyl-CoA dehydrogenase deficiency is at least 1 in 10,000-15,000 births. Avoidance of fasting and supplementation with carnitine may be lifesaving in these patients, who generally present in infancy.

Interference with fatty acid metabolism also underlies the fasting hypoglycemia associated with Jamaican vomiting sickness, with atractyloside, and with the drug valproate. In **Jamaican vomiting sickness** the unripe ackee fruit contains a water-soluble toxin, *hypoglycin*, which produces vomiting, CNS depression, and severe hypoglycemia. The hypoglycemic activity of hypoglycin derives from its inhibition of gluconeogenesis secondary to its interference with the acyl-CoA and carnitine metabolism essential for the oxidation of long-chain fatty acids. The disease is almost totally confined to Jamaica, where ackee forms a staple of the diet for the poor population. The ripe ackee fruit no longer contains this toxin.

Atractyloside is a reagent that inhibits oxidative phosphorylation in mitochondria by preventing the translocation of adenine nucleotides, such as ATP, across the mitochondrial membrane. Atractyloside is a perhydrophenanthrenic glycoside derived from *Atractylis gummifera*. This plant is found in the Mediterranean basin; ingestion of this "thistle" is associated with hypoglycemia and a syndrome similar to Jamaican vomiting sickness. A similar illness noted in India, the **acute toxic encephalopathy-hypoglycemic syndrome**, may be caused by litchi consumption. Litchi contains hypoglycin A and/or methylenecyclopropylglycine, which may inhibit fatty acid oxidation or gluconeogenesis.

The anticonvulsant drug **valproate** is associated with side effects, predominantly in young infants, which include a Reye-like syndrome, low serum carnitine levels, and the potential for fasting hypoglycemia.

In all these conditions, hypoglycemia *is not associated with ketonemia and ketonuria.*

Acute Alcohol Intoxication

The liver metabolizes alcohol as a preferred fuel, and generation of reducing equivalents during the oxidation of ethanol alters the reduced form of nicotinamide adenine dinucleotide:nicotinamide adenine dinucleotide ratio, which is essential for certain gluconeogenic steps. As a result, gluconeogenesis is impaired and hypoglycemia may ensue if glycogen stores are depleted by starvation or by preexisting abnormalities in glycogen metabolism. In toddlers who have been unfed for some time, even the consumption of small quantities of alcohol can precipitate these events. The hypoglycemia promptly responds to IV glucose, which should always be considered in a child who presents initially with coma or seizure, after taking a blood sample to determine glucose concentration. The possibility that child ingested alcoholic drinks must also be considered if there was a preceding evening party. A careful history allows the diagnosis to be made and may avoid needless and expensive hospitalization and investigation.

Salicylate Intoxication

See Chapter 77 .

Both hyperglycemia and hypoglycemia occur in children with salicylate intoxication. Accelerated utilization of glucose, resulting from augmentation of insulin secretion by salicylates, and possible interference with gluconeogenesis may contribute to hypoglycemia. Infants are more susceptible than older children. Monitoring of blood glucose levels with appropriate glucose infusion in the event of hypoglycemia should form part of the therapeutic approach to salicylate intoxication in childhood. Ketosis may occur.

Phosphoenolpyruvate Carboxykinase Deficiency

Deficiency of the rate-limiting gluconeogenic enzyme phosphoenolpyruvate carboxykinase is associated with severe fasting hypoglycemia and variable onset after birth. Hypoglycemia may occur within 24 hr after birth, and defective gluconeogenesis from alanine can be documented in vivo. Liver, kidney, and myocardium demonstrate fatty infiltration, and atrophy of the optic nerve and visual cortex may occur. Hypoglycemia may be profound. Lactate and pyruvate levels in plasma have been normal, but a mild metabolic acidosis may be present. The fatty infiltration of various organs is caused by increased formation of acetyl-CoA, which becomes available for fatty acid synthesis. Diagnosis of this rare entity can be made with certainty only through appropriate enzymatic determinations in liver biopsy material or molecular diagnosis. Avoidance of periods of fasting through frequent feedings rich in carbohydrate should be helpful because glycogen synthesis and breakdown are intact.

Pyruvate Carboxylase Deficiency

See Chapter 105.4 .

Other Enzyme Defects

Galactosemia (Galactose-1-Phosphate Uridyl Transferase Deficiency)

See Chapter 105.2 .

Fructose Intolerance (Fructose-1-Phosphate Aldolase Deficiency)

See Chapter 105.3 .

Acute hypoglycemia is caused by fructose-1-phosphate aldolase deficiency, which inhibits glycogenolysis via the phosphorylase system and of gluconeogenesis at the level of fructose-1,6-diphosphate aldolase. Affected individuals usually learn spontaneously to eliminate fructose from their diet.

Defects in Glucose Transporters

GLUT-1 Deficiency

Rarely, infants with a seizure disorder are found to have low CSF glucose concentrations despite normal plasma glucose. Lactate concentrations in CSF are low, suggesting decreased glycolysis rather than bacterial infection, which causes low CSF glucose with high lactate. The erythrocyte glucose transporter (GLUT-1) is defective, suggesting a similar defect in the brain glucose transporter responsible for the clinical features. A ketogenic diet reduces the severity of seizures by supplying an alternate source of brain fuel that bypassed the defect in glucose transport.

GLUT-2 Deficiency

Children with hepatomegaly, galactose intolerance, and renal tubular dysfunction **(Fanconi-Bickel syndrome)** have a deficiency of GLUT-2 of plasma membranes. In addition to liver and kidney tubules, GLUT-2 is also expressed in pancreatic β cells. Thus the clinical manifestations reflect impaired glucose release from liver and defective tubular reabsorption of glucose plus phosphaturia and aminoaciduria**.**

Systemic Disorders

Several systemic disorders are associated with hypoglycemia in infants and children. **Neonatal sepsis** is often associated with hypoglycemia, possibly as a result of diminished caloric intake with impaired gluconeogenesis. Similar mechanisms may apply to the hypoglycemia found in severely malnourished infants or those with severe malabsorption. **Hyperviscosity** with a central hematocrit >65% is associated with hypoglycemia in at least 10–15% of affected infants. **Falciparum malaria** is associated with hyperinsulinemia and hypoglycemia. Heart and renal failure are also associated with hypoglycemia, but the mechanism is obscure.

Diagnosis and Differential Diagnosis

Table 111.8 and Fig. 111.5 list the pertinent clinical and biochemical findings in the common childhood disorders associated with hypoglycemia. A careful and detailed history is essential in every suspected or documented case of hypoglycemia (see Table 111.7). Specific points to note include age at onset, temporal relation to meals or caloric deprivation, and a family history of prior infants known to have had hypoglycemia or of unexplained infant deaths.

In the 1st week of life, most infants have the transient form of neonatal hypoglycemia either as a result of prematurity/intrauterine growth restriction or by virtue of being born to diabetic mothers. The absence of a history of maternal diabetes, but the presence of macrosomia and the characteristic large plethoric appearance of an infant of a diabetic mother, should arouse the possibility of hyperinsulinemic hypoglycemia of infancy, probably resulting from a K_{ATP} channel defect that is familial (autosomal recessive) or sporadic. Decreased β-hydroxybutyrate, low FFAs, and plasma insulin concentration >5 μU/mL or C-peptide >0.5 ng/mL in the presence of documented hypoglycemia confirm this diagnosis. The presence of hepatomegaly should arouse suspicion of an enzyme deficiency such as glucose-6-phosphatase in glycogen storage disease (GSD) I or other GSDs; if a non–glucose-reducing sugar is present in the urine (e.g., Clinitest positive but Clinistix negative), galactosemia is most likely. In males, the presence of a microphallus suggests the possibility of hypopituitarism, which also may be associated with cholestatic jaundice in both sexes; evidence of a midline facial defect such as cleft palate also suggests possible hypopituitarism as the cause of hypoglycemia from deficiency in GH and/or cortisol. A high index of suspicion and awareness of hypoglycemia as the cause for unusual behavior of any sick newborn should prompt a **bedside glucose determination** . However, because glucose meters have an accuracy of only ±20%, any blood glucose value <60 mg/dL *must be confirmed* by a formal laboratory measurement that is performed without delay on a blood sample preserved in a tube that prevents glycolysis, which can cause spurious low values.

After the newborn period, clues to the cause of persistent or recurrent hypoglycemia may be obtained through a careful history, physical examination, and initial laboratory findings. The temporal relation of the hypoglycemia to food intake may suggest that the defect is one of gluconeogenesis, if symptoms occur 6 hr or more after meals. If hypoglycemia occurs shortly after meals, **hyperinsulinism** should be suspected and confirmed or excluded via measurement of β-hydroxybutyrate, insulin, C-peptide, and FFAs in a sample in which blood glucose is <55 mg/dL. The autosomal dominant forms of hyperinsulinemic hypoglycemia need to be considered, with measurement of glucose, insulin, and ammonia and careful history for other affected family members of any age. Measurement of IGFBP-1 may be useful; it is low in states of hyperinsulinism and high in other forms of hypoglycemia. The presence of hepatomegaly suggests one of the **enzyme deficiencies** in glycogen breakdown or in gluconeogenesis, as outlined in Table 111.8 . The absence of ketonemia or ketonuria at the initial presentation strongly suggests hyperinsulinism or a defect in fatty acid oxidation. In most other causes of hypoglycemia, with the exception of galactosemia and fructose intolerance, ketonemia and ketonuria are present at the time of fasting hypoglycemia. During hypoglycemia, serum should be obtained for determination of substrates, especially glucose, β-hydroxybutyrate, lactate, and FFAs, as well as hormones, especially insulin, C-peptide, cortisol, ACTH, and GH, followed by repeated measurement of glucose after an intramuscular or IV injection of glucagon, as outlined in Table 111.7 . Table 111.8 summarizes the interpretation of the findings. Hypoglycemia with ketonuria in children between ages 18 mo and 5 yr is most likely to be **ketotic hypoglycemia** , especially if hepatomegaly is absent. The ingestion of a toxin, including alcohol or salicylate, can usually be excluded rapidly by the history. Inadvertent or deliberate drug ingestion and errors in dispensing medicines should also be considered. Factitious disorder (Munchausen) by proxy should be considered when parents or other caregivers have access to insulin or insulin secretagogues—high insulin concentrations in the sample with low concentrations of C-peptide confirm exogenous insulin administration. Deliberate or accidental ingestion of drugs that stimulate endogenous insulin secretion will result in both high insulin and C-peptide concentrations and may require specialized laboratory methods that identify the offending substance.

When the history is suggestive, but acute symptoms are not present, a 24 hr supervised fast can usually provoke hypoglycemia and resolve the question of hyperinsulinism or other conditions (see Table 111.8). Such a fast rarely needs to be extended to 36 hr, and only in older children. Such a fast is contraindicated if a fatty acid oxidation defect is suspected; other approaches such as mass tandem spectrometry or molecular diagnosis, or both, should be considered. Because adrenal insufficiency may mimic ketotic hypoglycemia, plasma cortisol and ACTH levels should be determined at the time of documented hypoglycemia; increased buccal or skin pigmentation may provide the clue to primary adrenal insufficiency with elevated ACTH (melanocyte-stimulating hormone) activity. Short stature or a decrease in the growth rate may provide the clue to pituitary insufficiency involving GH as well as ACTH. Definitive tests of pituitary-adrenal function, such as the arginine-insulin stimulation test for GH, IGF-1, IGFBP-1, and cortisol release, may be necessary.

In the presence of hepatomegaly and hypoglycemia, a presumptive diagnosis of the enzyme defect can often be made through the clinical manifestations, presence of hyperlipidemia, acidosis, hyperuricemia, response to glucagon in the fed and fasted states, and response to infusion of various appropriate precursors (see Table 111.7). Table 111.8 summarizes these clinical findings and investigative approaches. Definitive diagnosis of the GSD may require molecular diagnosis (see Chapter 105.1). Occasional patients with all the manifestations of GSD are found to have normal enzyme activity. These definitive studies require special expertise available only in certain institutions.

Treatment

The prevention of hypoglycemia and its resultant effects on CNS development are critically important in the newborn period. For neonates with hyperinsulinism not associated with maternal diabetes, subtotal or focal pancreatectomy may be needed, unless hypoglycemia can be readily controlled with long-term diazoxide, with somatostatin analogs (e.g., octreotide), or with sirolimus. Other novel approaches for treating hyperinsulinemic hypoglycemia are being investigated.

Treatment of **acute symptomatic** neonatal or infant hypoglycemia includes IV administration of 2 mL/kg of 10% dextrose in water (D10W), followed by a continuous infusion of glucose at 6-8 mg/kg/min, adjusting the rate to maintain blood glucose levels in the normal range. If hypoglycemic seizures are present, some recommend a 4 mL/kg bolus of D10W.

Treatment of asymptomatic hypoglycemia in at-risk infants usually includes enteral feedings rather than parenteral glucose. If symptoms develop or the hypoglycemia persists despite enteral feedings, IV glucose is indicated. Dextrose gel (40% at 400 mg/kg) administered into the mouth may be an alternative to enteral feedings if breast milk or if formula is not available.

The management of **persistent** neonatal or infantile hypoglycemia includes increasing the rate of IV glucose infusion to 10-15 mg/kg/min or more, if needed. This may require a central venous or umbilical venous catheter to administer a hypertonic 15–25% glucose solution. If hyperinsulinism is present, it should be medically managed initially with diazoxide and then somatostatin analogs. If hypoglycemia is unresponsive to IV glucose plus diazoxide (maximal doses up to 15 mg/kg/day) and somatostatin analogs, partial or near-total pancreatectomy should be considered. Such surgery should be performed in centers with the requisite facilities and trained staff experienced in the procedures. If possible, surgery should be preceded by ^{18}F-L-DOPA scanning to localize a lesion which can then provide guidance to the surgeon for curative resection before the operation is undertaken.

Oral **diazoxide** , 5-15 mg/kg/24 hr in divided doses twice daily, may reverse hyperinsulinemic hypoglycemia but may also produce hirsutism, edema, nausea, hyperuricemia, electrolyte disturbances, advanced bone age, IgG deficiency, and rarely, hypertension with prolonged use. The long-acting somatostatin analog **octreotide** may be helpful in controlling hyperinsulinism causing hypoglycemia in patients with islet cell disorders, including genetic mutations in K_{ATP} channel and islet cell adenoma. In neonates and young infants, **glucagon** given by continuous IV infusion at 5 µg/kg/hr, together with octreotide, 20-50 µg/kg/day subcutaneously every 6-12 hr, may maintain blood glucose, but generally these agents are used as a temporizing measure before partial or more complete pancreatectomy. Potential but unusual complications of octreotide include poor growth because of impaired GH release, pain at the injection site, vomiting, diarrhea, and hepatic dysfunction (hepatitis, cholelithiasis), and necrotizing enterocolitis; tachyphylaxis to the drug's effects is more common. Octreotide may be particularly useful for the treatment of refractory hypoglycemia despite subtotal pancreatectomy.

Total pancreatectomy is not optimal therapy because of the risks of surgery, permanent diabetes mellitus, and exocrine pancreatic insufficiency. Continued prolonged medical therapy without pancreatic resection, if hypoglycemia is controllable, is worthwhile because over time some children have a spontaneous resolution of the hyperinsulinism-induced hypoglycemia. This should be balanced against the risk of hypoglycemia-induced CNS injury and the toxicity of drugs.

Prognosis

The prognosis is good in asymptomatic neonates with hypoglycemia of short duration. Hypoglycemia recurs in 10–15% of infants after adequate treatment. Recurrence is more common if IV fluids are extravasated or discontinued too rapidly before oral feedings are well tolerated. Children who had transient neonatal hypoglycemia have an increased incidence of ketotic hypoglycemia later in life.

The prognosis for normal intellectual function must be guarded because prolonged, recurrent, and severe symptomatic hypoglycemia is associated with neurologic sequelae. Symptomatic infants with hypoglycemia, particularly low-birthweight infants, those with persistent hyperinsulinemic hypoglycemia, and severely hypoglycemic infants born to poorly controlled diabetic mothers, have a poorer prognosis for subsequent normal intellectual development than asymptomatic infants.

CHAPTER 112

Overview of Morbidity and Mortality

James M. Greenberg

Infant Mortality

The **infant mortality rate** is a metric used by public health agencies, policymakers, and governments to gauge the overall quality of pediatric and population health among a given population residing within geographically defined boundaries. The rate is stated as the number of infant deaths per 1,000 live births. Specific definitions support each variable. In the United States, an *infant death* is defined as mortality taking place from the time after delivery at any gestational age, up to the 1st birthday. No age correction is made to account for a premature birth. Each infant death is assigned to a geographic entity (e.g., county, state, country) on the basis of the mother's home address at the time of death. The definition of a *live birth* is typically based on the complete expulsion of the productions of conception from the uterus and 1 of 3 criteria: detection of cardiac activity (by auscultation or palpation of the umbilical cord stump), definite movement generated by voluntary muscle contraction, or any respiratory effort. It is important to note that this definition does not incorporate any gestational age cutoff.

The risk of mortality and major morbidity is particularly high around the time of birth (Fig. 112.1). Therefore, within the spectrum of infant mortality, certain subcategories are used in maternal and child health practice to focus on specific periods of high risk. The **perinatal period** is typically defined as the time from the 28th wk of pregnancy through the 7th postpartum day. The **neonatal period** spans the 1st 28 days of life and can be further subdivided into *early neonatal* (1st 7 days) and *late neonatal* (days 8-28) (Fig. 112.2). The primary causes of mortality shift as infancy progresses: during the perinatal and neonatal periods, **preterm birth** (Fig. 112.3) and **congenital malformations** predominate, whereas **unsafe sleep practices** accounts for the majority of deaths during the remainder of infancy. In developing countries with limited resources, preterm birth remains a concern, but other causes, such as infection, birth asphyxia, and complications of labor and delivery, add an additional burden (see Fig. 112.2).

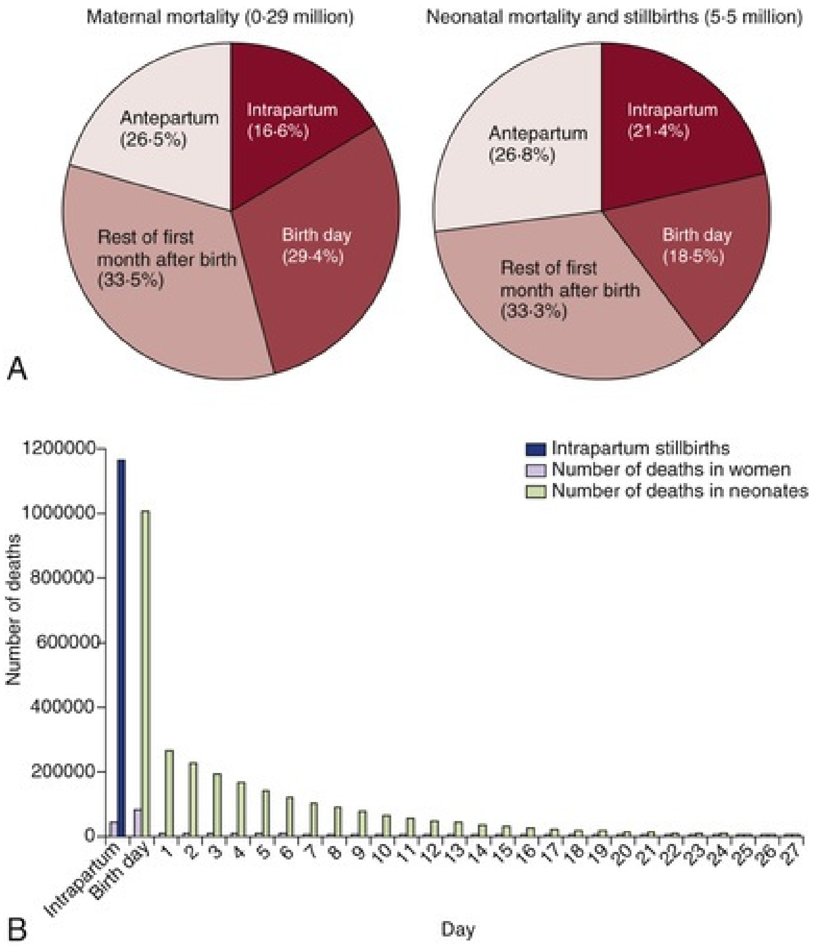

FIG. 112.1 **A,** Timing of death for women and their babies (third-trimester stillbirths and neonatal deaths) during pregnancy, birth, and the postnatal period. Includes all deaths of mothers and their babies from 28 wk of gestation up to 28 days of life. **B,** Number of deaths during labor and the 1st month after birth of women and their babies (intrapartum stillbirths and neonates). Insufficient data were available to accurately assign the day of death for the 1.4 million antepartum stillbirths and 63,000 maternal deaths occurring during the last trimester of pregnancy (before the onset of labor). (From Lawn JE, Blencowe H, Oza S, et al: Every newborn: progress, priorities, and potential beyond survival. Lancet 384:189–202, 2014, Fig 5.)

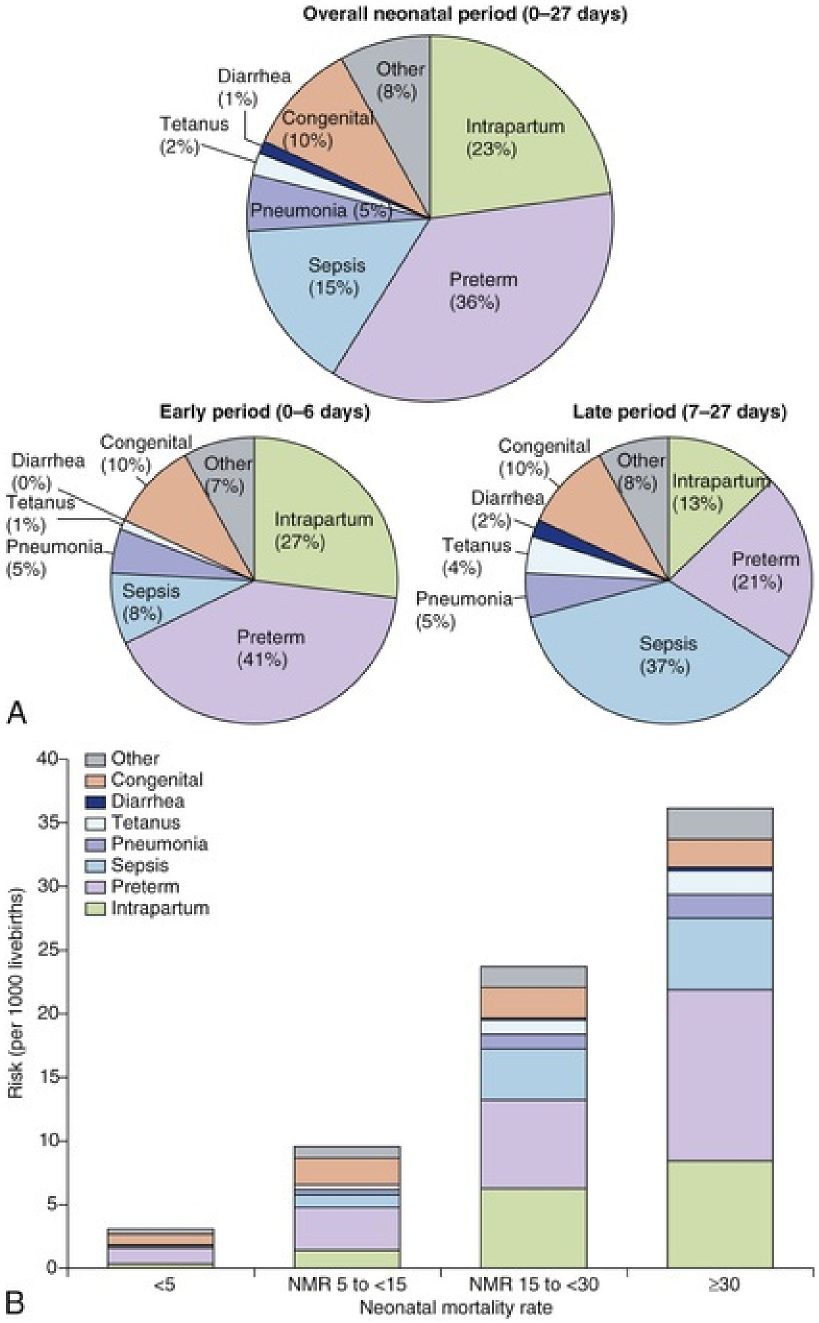

FIG. 112.2 **A,** Cause of death distribution for the neonatal period, and by the early (<7 days) and late (7–28 days) neonatal periods, for 194 countries in 2012. **B,** Variation in cause-specific neonatal mortality rates (NMRs) by level of NMR in 2012, showing risk difference by cause of death compared with the lowest mortality group (NMR <5). Data from Child Health Epidemiology Reference Group and World Health Organization (WHO) estimates for 194 countries for 2012. Estimates are based on multicause statistical models. In 2012, an additional estimated 196,000 deaths occurred in the postneonatal period from neonatal conditions (preterm birth, intrapartum related) and an estimated further 309,000 from term, small for gestational age. (From Lawn JE, Blencowe H, Oza S, et al: Every

newborn: progress, priorities, and potential beyond survival, Lancet 384:189–202, 2014, Fig 6.)

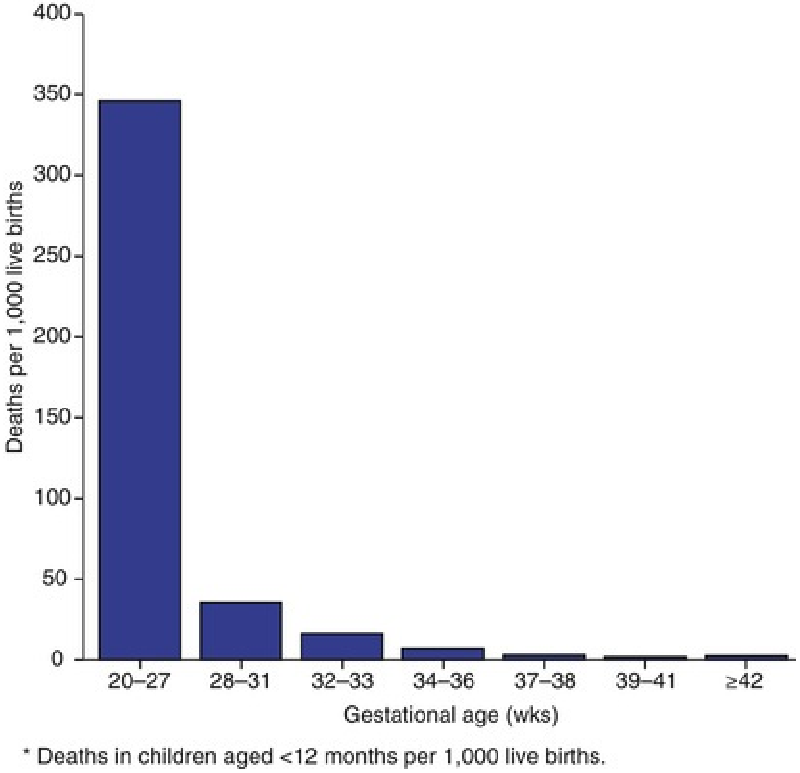

FIG. 112.3 Infant mortality rates by gestational age—United States, 2013. Deaths in children age <12 mo per 1,000 live births. (From Shapiro-Mendoza CK, Barfield WD, Henderson Z, et al: CDC Grand Rounds: Public health strategies to prevent preterm birth, MMWR 65(32):826–830, 2016, p 827.)

Rankings and Trends

Over the past century, infant mortality rates have declined in the United States and across most of the world. However, rates continue to differ worldwide (Fig. 112.4). In general, the highest rates are observed in low-resource, developing countries. However, the United States remains an anomaly among nations in the developed world. Table 112.1 shows infant mortality rates from a representative sample of developed countries. The rates are adjusted to exclude deaths before 24 wk gestation to account for potential variation in definitions of live births that might occur at the threshold of viability, to ensure comparability. Beginning in the 1980s, U.S. rates began to consistently exceed other developed nations; in 2015, U.S. infant mortality rates were >2-fold higher than in many developed countries. A wide range of infant mortality rates is also observed, with the highest rates in the Southeast United States and lower rates in the Upper Midwest, the Northeast, and the West Coast.

Major Causes of Infant Death

In the United States and Europe, most infant deaths fall into 1 of 3 major categories of causation: preterm birth, congenital malformations, and sleep related (e.g., SIDS). Infections, trauma, birth asphyxia, and injuries account for the remainder. The pattern differs in the developing world, where infections and asphyxia predominate. When considered based on the classification of infant cause of death by the *International Classification of Diseases, Tenth Revision* , congenital malformations are the leading cause, followed by disorders related to prematurity and low birthweight. Nonetheless, preterm birth rather than congenital malformations accounts for the majority of infant deaths in the United States, when deaths from unique complications of prematurity are included.

The U.S. preterm birth rate is substantially higher than in other developed countries and best explains elevated U.S. infant mortality rates. Worldwide, preterm birth rates display a tight concordance with infant mortality rates, providing further evidence for the importance of this linkage (Fig. 112.5). In the era of modern neonatal intensive care, most preterm birth deaths occur among the earliest gestational ages (<28 wk), and within the 1st few days of life, because of profound respiratory immaturity and insufficiency. The remaining preterm birth deaths result from morbidities associated with prematurity. Late preterm birth (35-36 wk gestation) is not a significant contributor to infant mortality.

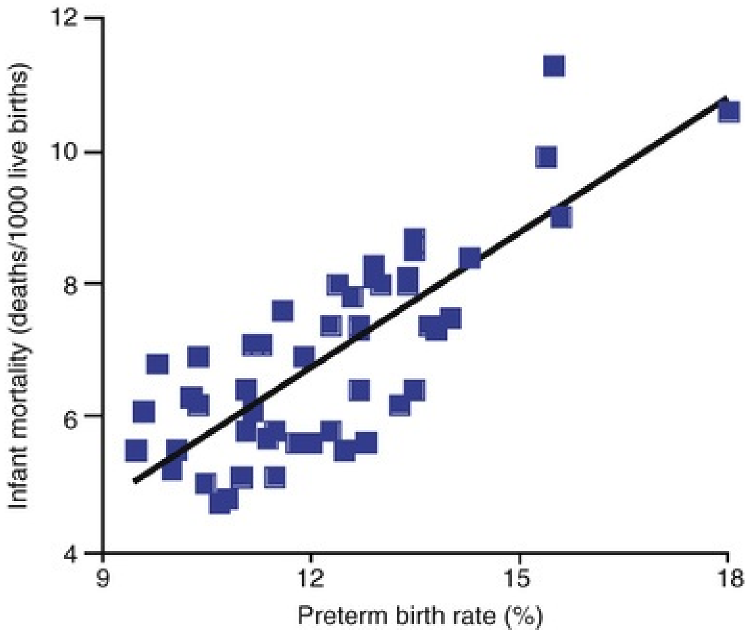

FIG. 112.5 Preterm birth as a function of infant mortality rates for 40 countries. (Data courtesy of L. Muglia, MD, PhD, Cincinnati Children's Research Foundation.)

International variation in live-birth registration practices may explain the elevated U.S. infant mortality. Although these technical explanations deserve further investigation, they should not be used to justify high U.S. infant mortality. In the United States, where live-birth registration practices are consistent, substantial variation in infant mortality and preterm birth rates implies *systemic* rather than technical explanations.

Racial Disparity and Infant Mortality

There is a significant disparity between infant mortality rates among U.S.-born white and black (African American) infants. This difference persists, even when socioeconomic status (SES) and educational levels are considered. The disparity is restricted to blacks; Hispanic populations in the United States tend to have infant mortality rates in line with the white population. Understanding this *Hispanic paradox* may provide insight into mechanisms driving the African American disparity. Interestingly, South Asian (Indian) populations in the United States may also have elevated infant mortality driven by low birthweight. Preterm birth and low birthweight are the key drivers of the black infant mortality disparity. Black preterm births rates are twice that of other U.S. racial and ethnic groups (Fig. 112.6), a gap that has persisted for decades. This is especially true for preterm birth rates at very low gestational ages, <28 wk, where mortality risks are high, even with the availability of modern neonatal intensive care units (NICUs). Racial disparities of mortality are not present among those receiving NICU care. Mechanistic explanations for the racial disparity remain elusive. Theories based on concepts of lifetime stress from experiences of racism or adverse life events are compelling (Chapter 2.1) However, studies focusing on stress and pregnancy outcomes fail to demonstrate clear mechanistic links.

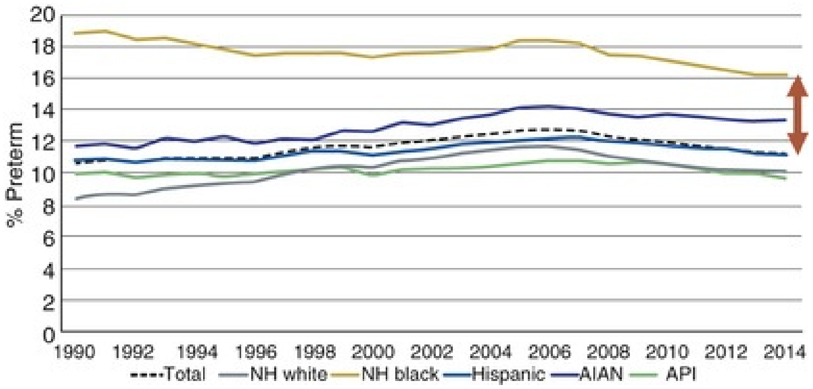

FIG. 112.6 The gap between black and white preterm birth rates in the United States has persisted for >3 decades. NH, Non-Hispanic; AIAN, American Indian/Alaskan Native; API, Asian/Pacific Islander. (Data from the National Center for Health Statistics.)

Congenital Malformations

Infant deaths from congenital malformations are the 2nd leading cause of infant death after premature birth. Many disorders reside in this category, with **congenital heart disease** the leading etiology. From a public health perspective, specific interventions can reduce the potential for certain congenital malformations, most notably periconceptional folic acid intake and appropriate vaccination programs to prevent diseases such as rubella during pregnancy. However, the mechanism of most congenital malformations remains poorly understood and therefore not yet amenable to population-based prevention strategies. In contrast to preterm birth, there is no discernible racial disparity for mortality caused by congenital malformations in the United States.

Sleep-Related Deaths (SUID, SIDS)

Sudden unexpected infant death (SUID) is a sudden and unexpected death during infancy. Following a thorough investigation of the death, SUID may be explained through mechanisms such as cosleeping and suffocation, or airway obstruction caused by soft objects or excessive bedding. **Sudden infant death syndrome (SIDS)** is a subcategory of SUID assigned to SUIDS that cannot be explained after a thorough investigation, including postmortem examination (see Chapter 402). SIDS represents a small fraction of all sleep-related deaths. With the advent of effective public health messaging, rates of sleep-related deaths in the United States have declined. However, a wide variation of rates is still observed across different geographic jurisdictions. SUID rates also display a racial disparity. The leading cause of infant death beyond the neonatal period is **unsafe infant sleep practices** .

Infant Mortality Reduction

Reduction of U.S. infant mortality is a challenging but attainable goal. Decreasing the preterm birth rate, especially extreme prematurity before 28 wk gestation, is an imperative. Improving our understanding of the biologic factors that control gestational duration and initiation of labor and delivery is key. Studies of intramuscular (but not vaginal) progesterone treatment during pregnancy for women known to be at elevated risk for a preterm birth have proved promising. However, the mechanism of action is not well understood, and the public health impact appears limited except perhaps for women with a previous preterm birth. Improving our understanding of how social determinants of health and health behavior influence birth outcomes is also important. **Smoking** during pregnancy is known to drive low birthweight, preterm birth, and elevated mortality. Improving interventions to eliminate smoking during pregnancy should reduce infant mortality. Understanding mechanistic links between the biology of parturition and the social and behavioral determinants of health is imperative.

Preterm Birth

Preterm birth is defined as a live birth occurring before the 37th wk of gestation. Comparison of preterm births between countries or other jurisdictions can be compromised by methods used to calculate gestational age. Three approaches are currently in use: **last menstrual period** (LMP), **obstetric estimate** (OE), and a **combined estimate** . The last defers to the LMP *unless* the value is missing from the vital record information or is extremely inconsistent with the recorded birthweight. In this circumstance (0.4% of record in 2013) the combined method uses the OE value. From a public health perspective, the OE offers superior validity. Since 2014 reports by federal agencies and stakeholder organizations (e.g., March of Dimes) use the OE to state preterm birth rates. The OE is typically a 1–2% lower preterm birth rate than the LMP or combined method. In 2016 the national preterm birth rate based on OE was 9.84%, compared to an 11.40% rate using the combined method.

The mortality and morbidity challenges encountered by a newborn delivered at 36 wk differ in severity from delivery at 25 wk. Subcategories of preterm birth corresponding to late (35-36 wk), moderate (32-34 wk), and early (<32 wk) acknowledge important differences in morbidity and mortality risk. From an infant mortality perspective, an additional subcategory of the early preterm population, *extreme preterm* births (<28 wk) has substantial importance, because >50% of all infant deaths occur in this population.

In addition to socioeconomic and racial factors, genetic variables may be associated with pregnancy duration and risk for preterm birth. Variants in *EBF1, EEFSEC, AGTR2, WNT4, ADCY5,* and *RAP2C* are reported to be associated with pregnancy length, whereas variants in *EBF1, EEFSEC,* and *AGTR2* loci are associated with preterm birth. In addition, 7 unrelated free RNA transcripts in maternal blood cells have been found to predict preterm delivery. These results are preliminary but may add specific targets for prevention of prematurity.

The Late Preterm Neonate

There is an important appreciation for the significance of late preterm delivery. Often these infants seem similar to their term counterparts, but epidemiologic data demonstrate that they are at significantly higher risk for apneic episodes, disorders of thermoregulation (e.g., hypothermia), hypoglycemia, respiratory distress, feeding difficulties, dehydration, and suspected sepsis. They are more likely to require NICU admission and experience an extended hospital stay. Late preterm neonates also appear to have a higher risk for longer-term neurologic problems, such as attention-deficit disorders and learning disabilities.

Late preterm deliveries may result from complications of pregnancy (e.g., chorioamnionitis, premature rupture of membranes) or maternal conditions (e.g., preeclampsia). Many are caused by elective delivery through induction of labor or scheduled cesarean birth during the late preterm period. As appreciation grew for an elevated morbidity and mortality risk in late preterm infants, a movement to eliminate elective deliveries before 39 wk gained national traction. The Ohio Perinatal Quality Collaborative initiated a statewide quality improvement initiative to eliminate elective deliveries before 39 wk of gestation through establishment of a multihospital learning network. Their work led to a material and sustained reduction of elective deliveries, with attendant reductions in neonatal morbidity and hospital length of stay.

The Moderate and Early Preterm Neonate

As gestational age at delivery declines, morbidity and mortality risks increase. With modern neonatal intensive care, the potential for survival at a given gestational age has improved. With that, the *threshold* gestational age for offering comprehensive neonatal intensive care has correspondingly declined. However, assigning a specific gestational age for threshold of viability remains a challenging problem. Current published data suggest minimal life-sustaining impact for neonatal intensive care offered before 22-23 wk gestation. However, covariables such as birthweight and perhaps exposure to antenatal steroids must be considered. Neonates born at extremely early gestational ages are at very high risk for morbidities carrying lifelong consequences. Major morbidities of prematurity contribute to infant mortality after the early neonatal period (e.g., BPD, IVH, NEC, PDA). All are more common in extremely premature infants, and when present, each can prolong NICU length of stay or may be listed as an immediate cause of death. Therefore, multidisciplinary decision-making with direct family participation is essential.

Preterm neonates at moderate and early gestational ages are at elevated risk for all the complications of late prematurity. Additional categories of morbidity that are absent or extremely rare in the late preterm and term populations also become much more common at earlier gestational ages (Table 112.2). These include adverse **neurodevelopmental** sequelae such as cerebral palsy, periventricular leukomalacia, intraventricular hemorrhage, hydrocephalus, visual impairment, and hearing impairment. Problems affecting other major organ systems include bronchopulmonary dysplasia, necrotizing enterocolitis, and patent ductus arteriosus. Early preterm infants are at the highest risk for these complications, which also tend to be more severe.

Table 112.2

Major Morbidities of the Neonate and Associated Etiologic Conditions

MORBIDITIES	EXAMPLES OF ETIOLOGY
CENTRAL NERVOUS SYSTEM	
Spastic diplegic/quadriplegic cerebral palsy	HIE, periventricular leukomalacia, undetermined factors
Choreoathetotic cerebral palsy	Kernicterus/bilirubin encephalopathy
Microcephaly	Intrauterine infections
Hydrocephalus	IVH, HIE, meningitis
Seizures	HIE, encephalopathies, hypoglycemia
Learning disorders, developmental delay	Prematurity, HIE, hypoglycemia, IVH
SENSATION—PERIPHERAL NEUROPATHIES	
Visual impairments	Retinopathy of prematurity, congenital viral infection
Strabismus	Opioid exposure, undetermined
Hearing impairment	HIE, bilirubin toxicity, drug toxicity (loop diuretics, aminoglycosides)
Speech delay	Prematurity, prolonged endotracheal intubation, hearing loss
Paralysis, paresis	Birth trauma (usually affected: phrenic nerve, brachial plexus, spinal cord)
RESPIRATORY SYSTEM	
Bronchopulmonary dysplasia	Prematurity, positive pressure ventilation, oxygen exposure
Subglottic stenosis	Prolonged endotracheal intubation
Sudden unexpected infant death	Prematurity, unsafe sleep conditions
Choanal stenosis, nasal septum injury	Prolonged nasotracheal intubation, nasal CPAP
CARDIOVASCULAR SYSTEM	
Cyanosis	Pulmonary hypertension, cor pulmonale, severe BPD
Heart failure	PDA, congenital heart defects with left-to-right shunting
GASTROINTESTINAL SYSTEM	
Short gut syndrome	NEC, malrotation with mid-gut volvulus, bowel atresia
Cholestatic liver disease	Injury from prolonged parenteral nutrition, sepsis, short gut syndrome
Failure to thrive	Short gut syndrome, BPD, cyanotic heart disease
Inguinal hernia	Preterm birth, male gender, positive pressure ventilation
MISCELLANEOUS	
Cutaneous scarring	Cutis aplasia, chest tube placement
Hypertension	Renal thrombi, prolonged umbilical artery catheterization, unknown

BPD, Bronchopulmonary dysplasia; CPAP, continuous positive airway pressure; HIE, hypoxia-ischemic encephalopathy; IVH, intraventricular hemorrhage; NEC, necrotizing colitis; PDA, patent ductus arteriosus.

Intraventricular hemorrhage (IVH) occurs when the very fragile capillaries of the periventricular white matter and choroid plexus rupture. The typical pathophysiology is accumulation of blood in the lateral ventricles, which can lead to obstruction of cerebrospinal fluid circulation and ultimately hydrocephalus.

Bronchopulmonary dysplasia (BPD) is a complication of respiratory distress syndrome and prematurity leading to reactive airway disease, alveolar insufficiency, and in severe cases, pulmonary hypertension and death. BPD remains the most common morbidity of prematurity among NICU survivors. The most powerful predictor of BPD is gestational age: as gestational age decreases, the risk of BPD increases. Oxygen exposure and treatment with positive pressure ventilation also increase the risk of developing BPD at any gestational age.

Necrotizing enterocolitis (NEC) is a devastating inflammatory process that can occur anywhere in the lower gastrointestinal tract, most often at the distal ilium and ascending colon. In approximately 40% of patients, surgical exploration and resection of necrotic bowel is required, increasing potential for failure to thrive, malabsorption, and short bowel syndrome. Those at the lowest gestational ages are at the highest risk. Interestingly, preterm infants at the earliest gestational ages tend to develop NEC later in their hospital course than moderate or late preterm infants, suggesting a developmental window of susceptibility.

Patent ductus arteriosus (PDA) is a common finding in preterm neonates born before 28 wk. The ductus arteriosus must be patent during intrauterine life to sustain fetal circulation. Under normal physiologic conditions, the ductus undergoes functional closure within a few minutes of parturition. However, under conditions of marginal oxygenation and ventilation, ductal closure in preterm infants may be delayed. If ductal patency persists, it can promote pulmonary overcirculation, complicating the management of respiratory disease.

Low Birthweight, Intrauterine Growth Restriction, and Small for Gestational Age

Low birthweight (LBW) is classified as any live birth <2,500 g. The **very-low-birthweight (VLBW)** subcategory corresponds to <1,500 g. In general, LBW and VLBW infants are also preterm, although other intrauterine conditions discussed below also contribute. **Intrauterine growth restriction (IUGR)** refers to deficiency of fetal growth and an abnormal fetal growth trajectory. Etiologies of IUGR include certain congenital infections (e.g., rubella, cytomegalovirus), placental insufficiency, environmental factors (e.g., maternal smoking), and certain congenital conditions (e.g., aneuploidy). In contrast, **small-for-gestational-age (SGA)** neonates are constitutionally normal, without known genetic abnormalities or pathologic conditions. SGA and IUGR may occur at any gestational age. Birthweight and gestational age combine to predict mortality and morbidity risk at any gestational age. Healthcare providers can use an online mortality calculator developed by the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network that incorporates gestational age and birthweight to assist with prenatal counseling for families anticipating a preterm delivery.

CHAPTER 113

The Newborn Infant

Neera K. Goyal

See also Chapter 21 .

Although the neonatal period is a highly vulnerable time as infants complete the many physiologic adjustments required for extrauterine existence, this transition is uneventful for most full-term infants. Management of the newborn should focus on parental anticipatory guidance and early detection of conditions or complications that carry risk of morbidity or even death.

113.1

History in Neonatal Pediatrics

Neera K. Goyal

Assessment of the newborn should begin with a review of the maternal and family history, the pregnancy, and the delivery. Details of this history should include the following information, which will guide further evaluation and management in the newborn period:

◆ Demographic and social data (socioeconomic status, age, race, prenatal care utilization, substance use). Newborns whose mothers are young (<18 yr old) or who have concerns regarding housing, food insecurity, or access to healthcare may warrant evaluation by a social worker or case manager. Newborns exposed in utero to substances such as alcohol, cocaine, nicotine, caffeine, and opioids should be evaluated for associated symptoms (see Chapter 126).

◆ Maternal medical conditions (cardiopulmonary disorders, infectious diseases, genetic disorders, anemia, diabetes mellitus, current medications). Newborns of diabetic mothers warrant screening within the 1st 24 hr of life for severe hypoglycemia (see Chapter 127.1).

◆ Past medical illnesses in the mother and family, including previous siblings with a history of jaundice (see Chapter 123.3).

◆ Previous maternal reproductive problems: stillbirth, prematurity, blood group sensitization (see Chapter 124).

◆ Events occurring in the present pregnancy (prenatal laboratory and imaging results, preterm labor, fetal assessments, vaginal bleeding, acute illness, duration of rupture of membranes). Such information may prompt additional newborn testing, such as rapid plasma reagin (RPR) testing in the case of a positive maternal syphilis screen, or renal ultrasound imaging if fetal pyelectasis was detected prenatally.

◆ Description of the labor (duration, fetal presentation, fetal distress, fever) and delivery (cesarean section, anesthesia or sedation, use of forceps, Apgar scores, need for resuscitation). This information, combined with clinical assessment of the newborn, will determine risk for clinical deterioration and need for further monitoring and intervention.

113.2

Physical Examination of the Newborn Infant

Neera K. Goyal

Many physical and behavioral characteristics of a normal newborn infant are described in Chapter 21 .

The **initial examination** of a newborn infant should be performed as soon as possible after delivery. Temperature, pulse, respiratory rate, color, signs of respiratory distress, tone, activity, and level of consciousness of infants should be monitored frequently until stabilization. For high-risk deliveries, this examination should take place in the delivery room and should focus on congenital anomalies, maturation and growth, and pathophysiologic problems that may interfere with normal cardiopulmonary and metabolic adaptation to extrauterine life. Congenital anomalies of varying degrees of severity may be present in 3–5% of infants. After a stable delivery room course, a second and more detailed examination should be performed within 24 hr of birth.

If an infant remains in the hospital longer than 48 hr, repeat assessments should be performed throughout the hospital stay including a discharge examination within 24 hr of discharge. For a healthy infant, the mother should be present during this examination; even minor, seemingly insignificant anatomic variations may worry the parents and should be explained. The explanation must be careful and skillful so that otherwise unworried parents are not unduly alarmed. Infants should not be discharged from the hospital without a final examination because certain abnormalities, particularly cyanosis and heart murmurs, often appear or disappear in the immediate neonatal period; in addition, evidence of disease that has just been acquired may be noted. The pulse (normal: 120-160 beats/min), respiratory rate (normal: 30-60 breaths/min), temperature, weight, length, head circumference, and dimensions of any visible or palpable structural abnormality should be assessed. Blood pressure is determined if a neonate appears ill or has a heart murmur. Pulse oximetry should be performed to screen for critical congenital heart disease and is part of the routine screening for newborn infants.

Examining a newborn requires patience, gentleness, and procedural flexibility. Thus, if the infant is quiet and relaxed at the beginning of the examination, palpation of the abdomen or auscultation of the heart should be performed first, before other, more intrusive manipulations are attempted.

General Appearance

Physical activity may be decreased by the effects of illness or drugs; an infant may be either lying with the extremities motionless, to conserve energy for the effort of difficult breathing, or vigorously crying, with accompanying activity of the arms and legs. Both active and passive muscle tone and any unusual posture should be noted. Coarse, tremulous movements with ankle or jaw **myoclonus** are more common and less significant in newborn infants than at any other age. Such movements tend to occur when an infant is active, whereas convulsive twitching usually occurs in a quiet state. **Edema** may produce a superficial appearance of good nutrition. Pitting after applied pressure may or may not be noted, but the skin of the fingers and toes lacks the normal fine wrinkles when filled with fluid. Edema of the eyelids commonly results from irritation caused by the administration of silver nitrate. Generalized edema may occur with prematurity, hypoproteinemia secondary to severe erythroblastosis fetalis, nonimmune hydrops, congenital nephrosis, Hurler syndrome, and from unknown causes. Localized edema suggests a congenital malformation of the lymphatic system; when confined to one or more extremities of a female infant, it may be the initial sign of Turner syndrome (see Chapters 98 and 604).

Skin

Vasomotor instability and peripheral circulatory sluggishness are revealed by deep redness or purple lividity in a crying infant, whose color may darken profoundly with closure of the glottis preceding a vigorous cry, and by harmless cyanosis (**acrocyanosis**) of the hands and feet, especially when they are cool. Mottling, another example of general circulatory instability, may be associated with serious illness or related to a transient fluctuation in skin temperature. An extraordinary division of the body from the forehead to the pubis into red and pale halves is known as *harlequin color change* , a transient and harmless condition. Significant **cyanosis** may be masked by the pallor of circulatory failure or anemia; alternatively, the relatively high hemoglobin content of the 1st few days and the thin skin may combine to produce an appearance of cyanosis at a higher partial pressure of arterial oxygen (Pa_{O_2}) than in older children. Localized cyanosis is differentiated from *ecchymosis* by the momentary blanching pallor (with cyanosis) that occurs after pressure. The same maneuver also helps in demonstrating icterus. **Pallor** may be caused by anemia, asphyxia, shock, or edema. Early recognition of anemia may lead to a diagnosis of fetomaternal blood transfusion, erythroblastosis fetalis, subcapsular hematoma of the liver or spleen, subdural hemorrhage, or fetal-maternal or twin-twin transfusion. Without being anemic, postmature infants tend to have paler and thicker skin than term or premature infants. The ruddy appearance of plethora is seen with polycythemia.

The vernix and common transitory macular capillary hemangiomas of the eyelids and neck are described in Chapter 669 . Cavernous hemangiomas are deeper, blue masses that, if large, may trap platelets and produce disseminated intravascular coagulation or interfere with local organ function. Scattered petechiae may be seen on the presenting part (usually the scalp or face) after a difficult delivery. Slate-blue, well-demarcated areas of pigmentation called **mongolian spots** are seen over the buttocks, back, and sometimes other parts of the body in more than 50% of black, Native American, and Asian infants, and occasionally in white infants. These benign patches have no known anthropologic significance despite their name; they tend to disappear within the 1st year. The vernix, skin, and especially the cord may be stained brownish yellow if the amniotic fluid has been colored by the passage of meconium during or before birth.

The skin of premature infants is thin and delicate and tends to be deep red; in extremely premature infants, the skin appears almost gelatinous and translucent. Fine, soft, immature hair called **lanugo** frequently covers the scalp and brow and may also cover the face of premature infants. Lanugo has usually been lost or replaced by vellus hair in term infants. **Tufts of hair** over the lumbosacral spine suggest an underlying abnormality, such as occult spina bifida, a sinus tract, or a tumor. The nails are rudimentary in very premature infants, but they may protrude beyond the fingertips in infants born past term. Postterm infants may have a peeling, parchment-like skin (Fig. 113.1), a severe degree of which may mimic **ichthyosis congenita** (see Chapter 677).

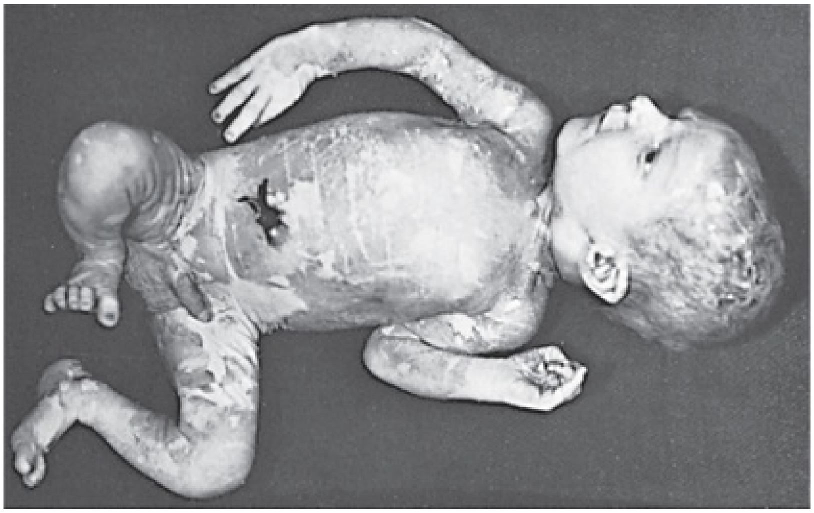

FIG. 113.1 **Infant with intrauterine growth restriction as a result of placental insufficiency. Note the long, thin appearance with peeling, parchment-like dry skin, alert expression, meconium staining of the skin, and long nails. (From Clifford S: *Advances in pediatrics,* vol 9, Chicago, 1962, Year Book.)**

In many neonates, small, white papules on an erythematous base develop 1-3 days after birth. This benign rash, **erythema toxicum** , persists for as long as 1 wk, contains eosinophils, and is usually distributed on the face, trunk, and extremities (see Chapter 666). **Pustular melanosis** , a benign lesion seen predominantly in black neonates, contains neutrophils and is present at birth as a vesiculopustular eruption around the chin, neck, back, extremities, and palms or soles; it lasts 2-3 days. Both lesions need to be distinguished from more dangerous vesicular eruptions such as herpes simplex (see Chapter 279) and staphylococcal disease of the skin (Chapter 208.1).

Amniotic bands may disrupt the skin, extremities (amputation, ring constriction, syndactyly), face (clefts), or trunk (abdominal or thoracic wall defects). Their cause is uncertain but may be related to amniotic membrane rupture or vascular compromise with fibrous band formation. Excessive skin fragility and extensibility with joint hypermobility suggest Ehlers-Danlos syndrome (see Chapter 679), Marfan syndrome (Chapter 722), congenital contractural arachnodactyly, and other disorders of collagen synthesis.

Skull

The skull may be molded, particularly if the infant is the first-born and if the head has been engaged in the pelvic canal for a considerable time. **Caput succedaneum** , caused by scalp pressure from the uterus, cervix, or pelvis, appears as a circular boggy area of edema with indistinct borders and often with overlying ecchymosis. A **cephalohematoma** presents as a well-circumscribed fluid-filled mass that does not cross suture lines. Unlike caput succedaneum, cephalohematoma is often not present at delivery but develops over the 1st few hr of life. Both cephalohematoma and caput succedaneum must be distinguished from a **subgaleal hemorrhage** , which is not restricted by the boundaries of the sutures and therefore is larger and more diffuse. Subgaleal hemorrhage requires prompt recognition because extensive bleeding may result in hypovolemic shock, with estimated mortality up to 20%. The head circumference of all newborns should be plotted on a growth chart to identify an excessively small head (**microcephaly**) or excessively large head (**megalencephaly**). The diagnostic differential for microcephaly is broad and includes underlying genetic disorders, congenital infection, and intrauterine drug exposure (see Chapter 609). Megalencephaly can suggest hydrocephaly, storage disease, achondroplasia, cerebral gigantism, neurocutaneous syndromes, or inborn errors of metabolism, or it may be familial. The suture lines and the size and fullness of the anterior and posterior fontanels should be determined digitally by palpation. The parietal bones tend to override the occipital and frontal bones. Premature fusion of sutures (**cranial synostosis**) is identified as a hard nonmovable ridge over the suture and an abnormally shaped skull. Great variation in the size of the **fontanels** exists at birth; if small, the anterior fontanel usually tends to enlarge during the 1st few mo after birth. The persistence of excessively large anterior (normal: 20 ±10 mm) and posterior fontanels has been associated with several disorders (Table 113.1). Persistently small fontanels suggest microcephaly, craniosynostosis, congenital hyperthyroidism, or wormian bones; presence of a 3rd fontanel suggests trisomy 21 but is seen in preterm infants. Soft areas (**craniotabes**) are occasionally found in the parietal bones at the vertex near the sagittal suture; they are more common in preterm infants and in infants who have been exposed to uterine compression. Although such soft areas are usually insignificant, their possible pathologic cause should be investigated if they persist. Soft areas in the occipital region suggest the irregular calcification and wormian bone formation associated with osteogenesis imperfecta, cleidocranial dysostosis, lacunar skull, cretinism, and occasionally Down syndrome.

Table 113.1

Disorders Associated with a Large Anterior Fontanel

Hypothyroidism
Achondroplasia
Apert syndrome
Cleidocranial dysostosis
Congenital rubella syndrome
Hallermann-Streiff syndrome
Hydrocephaly
Hypophosphatasia
Intrauterine growth restriction
Kenny syndrome
Osteogenesis imperfecta
Prematurity
Pyknodysostosis
Russell-Silver syndrome
Trisomies 13, 18, and 21
Vitamin D deficiency rickets

Atrophic or alopecic scalp areas may represent **aplasia cutis congenita** , which may be sporadic, or autosomal dominant, or associated with trisomy 13, chromosome 4 deletion, or Johanson-Blizzard syndrome. **Deformational plagiocephaly** may be the result of in utero positioning forces on the skull and manifests as an asymmetric skull and face with ear malalignment (see Chapter 610). It is associated with torticollis and vertex positioning. Depression of the skull (indentation, fracture, Ping-Pong ball deformity) is usually of prenatal onset and a result of prolonged focal pressure by the maternal pelvic bone.

Face

The general appearance of the face should be noted with regard to **dysmorphic features** , such as epicanthal folds, widely or narrowly spaced eyes, microphthalmos, asymmetry, long philtrum, and low-set ears, which are often associated with congenital syndromes. The face may be asymmetric as a result of a 7th nerve palsy, hypoplasia of the depressor muscle at the angle of the mouth, or an abnormal fetal posture (see Chapter 128); when the jaw has been held against a shoulder or an extremity during the intrauterine period, the mandible may deviate strikingly from the midline. Symmetric facial palsy suggests absence or hypoplasia of the 7th nerve nucleus (**Möbius syndrome**).

Eyes

The eyes often open spontaneously if the infant is held up and tipped gently forward and backward. This maneuver, a result of labyrinthine and neck reflexes, is more successful for inspecting the eyes than is forcing the lids apart. Conjunctival and retinal hemorrhages are usually benign. Retinal hemorrhages are more common with vacuum- or forceps-assisted deliveries than spontaneous vaginal delivery and least common after cesarean section. They are usually bilateral, intraretinal, and in the posterior pole. They resolve in most infants by 2 wk of age (85%) and in all infants by 4 wk. **Pupillary reflexes** are present after 28-30 wk of gestation. The iris should be inspected for colobomas and heterochromia. A cornea >1 cm in diameter in a term infant (with photophobia and tearing) or corneal clouding suggests congenital glaucoma and requires prompt ophthalmologic consultation. The presence of bilateral red reflexes suggests the absence of cataracts and intraocular pathology (see Chapter 637). **Leukokoria** (white pupillary reflex) suggests cataracts, tumor, chorioretinitis, retinopathy of prematurity, or a persistent hyperplastic primary vitreous and warrants an immediate ophthalmologic consultation (see Chapter 640).

Ears

Deformities of the pinnae are occasionally seen. Unilateral or bilateral preauricular skin tags occur frequently; if pedunculated, they can be tightly ligated at the base, resulting in dry gangrene and sloughing. The tympanic membrane, easily seen otoscopically through the short and straight external auditory canal, normally appears dull gray.

Nose

The nose may be slightly obstructed by mucus accumulated in the narrow nostrils. The nares should be symmetric and patent. Dislocation of the nasal cartilage from the vomerian groove results in asymmetric nares. Anatomic obstruction of the nasal passages secondary to unilateral or bilateral choanal atresia results in respiratory distress.

Mouth

A normal mouth may rarely have precocious dentition, with natal (present at birth) or neonatal (eruption after birth) teeth in the lower incisor position or aberrantly placed; these teeth are shed before the deciduous ones erupt (see Chapter 333). Alternatively, such teeth occur in Ellis–van Creveld, Hallermann-Streiff, and other syndromes. Extraction is not usually indicated. Premature eruption of deciduous teeth is even more unusual. The soft and hard palate should be inspected and palpated for a complete or submucosal cleft, and the contour noted if the arch is excessively high or the uvula is bifid. On the hard palate on either side of the raphe, there may be temporary accumulations of epithelial cells called **Epstein pearls** . Retention cysts of similar appearance may also be seen on the gums. Both disappear spontaneously, usually within a few weeks of birth. Clusters of small, white or yellow follicles or ulcers on erythematous bases may be found on the anterior tonsillar pillars, most frequently on the 2nd or 3rd day of life. Of unknown cause, they clear without treatment in 2-4 days.

Neonates do not have active salivation. The tongue appears relatively large; the frenulum may be short, but its shortness (**tongue-tie** or **ankyloglossia**) is rarely a reason for cutting it. If there are problems with feedings (breast or bottle) and the frenulum is short, frenulectomy (**frenotomy**) may be indicated. Frenotomy may reduce maternal nipple pain and improve breastfeeding scores more rapidly than no treatment, but over time, neonates not treated with frenotomy also have successful feeding. The sublingual mucous membrane occasionally forms a prominent fold. The cheeks have fullness on both the buccal and the external aspects as a result of the accumulation of fat in the sucking pads. These pads, as well as the labial tubercle on the upper lip (**sucking callus**), disappear when suckling ceases. A marble-sized buccal mass is usually caused by benign idiopathic fat necrosis.

The throat of a newborn infant is difficult to see because of the low arch of the palate; it should be clearly viewed because posterior palatal or uvular clefts are easy to miss. The tonsils are small.

Neck

The neck appears relatively short. Abnormalities are not common but include goiter, cystic hygroma, branchial cleft cysts, teratoma, hemangioma, and lesions of the sternocleidomastoid muscle that are presumably traumatic or caused by a fixed positioning in utero that produces either a hematoma or fibrosis, respectively. Congenital **torticollis** causes the head to turn toward and the face to turn away from the affected side (see Chapter 700.1). Plagiocephaly, facial asymmetry, and hemihypoplasia may develop if it is untreated (see Chapter 610). Redundant skin or webbing in a female infant suggests intrauterine lymphedema and Turner syndrome (see Chapters 98 and 604). Both clavicles should be palpated for fractures.

Chest

Breast hypertrophy is common, and milk may be present (but should not be expressed). Asymmetry, erythema, induration, and tenderness suggest mastitis or a breast abscess. Supernumerary nipples, inverted nipples, or widely spaced nipples with a shield-shaped chest may be seen; the last finding suggests Turner syndrome.

Lungs

Much can be learned by observing breathing. Normal variations in rate and rhythm are characteristic and fluctuate according to the infant's physical activity, the state of wakefulness, or the presence of crying. Because fluctuations are rapid, the **respiratory rate** should be counted for a full minute with the infant in the resting state, preferably asleep. Under these circumstances, the usual rate for normal term infants is 30-60 breaths/min; in premature infants the rate is higher and fluctuates more widely. A rate consistently >60 breaths/min during periods of regular breathing that persists for >1 hr after birth is an indication to rule out pulmonary, cardiac, or metabolic disease (acidosis) etiologies. Preterm infants may breathe with a Cheyne-Stokes rhythm, known as **periodic respiration** , or with complete irregularity. Irregular gasping, sometimes accompanied by spasmodic movements of the mouth and chin, strongly indicates serious impairment of the respiratory centers.

The breathing of newborn infants at rest is almost entirely *diaphragmatic*, so during inspiration, the soft front of the thorax is usually drawn inward while the abdomen protrudes. If the baby is quiet, relaxed, and with good color, this “paradoxical movement” does not necessarily signify insufficient ventilation. On the other hand, labored respiration with retractions is important evidence of respiratory distress syndrome, pneumonia, anomalies, or mechanical disturbance of the lungs. A weak, persistent or intermittent groaning, whining cry, or **grunting** during expiration can signify potentially serious cardiopulmonary disease or sepsis and warrants immediate attention. When benign, the grunting resolves 30-60 min after birth. Flaring of the alae nasi and retraction of the intercostal muscles and sternum are common signs of pulmonary pathology.

Normally, the breath sounds are *bronchovesicular.* Suspicion of pulmonary pathology because of diminished breath sounds, rhonchi, retractions, or cyanosis should always be verified with a chest radiograph.

Heart

Normal variation in the size and shape of the chest makes it difficult to estimate the size of the heart. The location of the heart should be determined to detect **dextrocardia** . The pulse is usually 110-140 beats/min at rest but may vary normally from 90 beats/min in relaxed sleep to 180 beats/min during activity. The still higher rate of supraventricular tachycardia (>220 beats/min) may be determined better with a cardiac monitor or electrocardiogram (ECG) than by auscultation. Preterm infants usually have a higher resting heart rate, up to about 160 beats/min, but may have a sudden onset of sinus bradycardia secondary to apnea. On both admission to and discharge from the nursery, the infant's pulses should be palpated in the upper and lower extremities to detect **coarctation of the aorta** . Transitory murmurs usually represent a closing ductus arteriosus. Although congenital heart disease (CHD) may not initially produce a murmur, a substantial portion of infants in whom persistent murmurs are detected during routine neonatal examination have underlying malformation. Routine screening for critical CHD using pulse oximetry is performed between 24 and 48 hr of life, which overall yields a sensitivity approaching 80% and specificity >99%. Pulse oximetry screening with SO_2 of ≥95% in the right hand or either foot and <3% difference between the right hand and foot is considered a normal screening test. Those with SO_2 <95% should be referred for evaluation and possible echocardiogram (see Chapter 452). Blood pressure (BP) measurements are indicated in the evaluation of ill-appearing infants and those in whom CHD is suspected. The oscillometric method is the easiest and most accurate noninvasive method available. Mean BP values vary by gestational age, however for all neonates, BP is expected to rise in the 1st 72 hr after birth (Fig. 113.2).

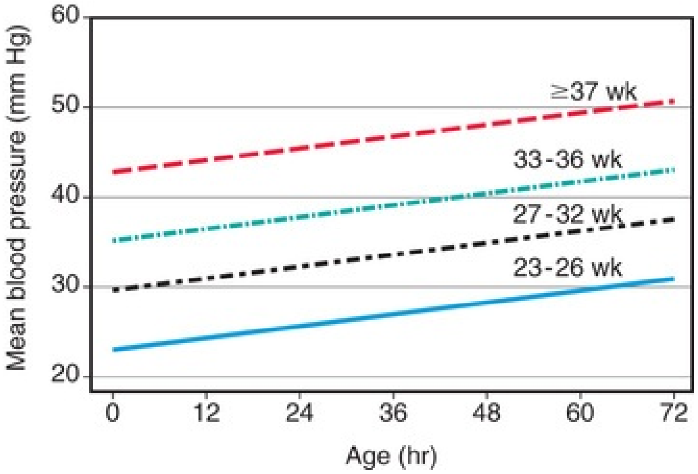

FIG. 113.2 **Nomogram for mean blood pressure (BP) in neonates with gestational ages of 23-43 wk. Derived from continuous arterial BP measurements obtained from 103 infants admitted to the neonatal intensive care unit. The graph shows the predicted mean BP of neonates of different gestational ages during the 1st 72 hr of life. Each line represents the lower limit of the 80% confidence interval (2-tail) of the mean BP for each gestational age-group; 90% of infants for each gestational age-group will be expected to have a mean BP value equal to or above the value indicated by the corresponding line, the lower limit of the confidence interval. (From Nuntnarumit P, Yang W, Bada-Ellzey SB: Blood pressure measurements in the newborn, *ClinPerinatol* 26:976–996, 1999.)**

Abdomen

The liver is usually palpable, sometimes as much as 2 cm below the rib margin. Less often, the tip of the spleen may be felt. The approximate size and location of each kidney can usually be determined on deep palpation. At no other period of life does the amount of air in the gastrointestinal tract vary so much, nor is it usually so great under normal circumstances. The intestinal tract is gasless at birth. Gas is swallowed soon after birth, and gas should normally be present in the rectum on radiograph by 24 hr of age. The abdominal wall is normally weak (especially in premature infants), and diastasis recti and umbilical hernias are common, particularly among black infants.

Unusual masses should be investigated immediately with ultrasonography. Renal pathology is the cause of most neonatal abdominal masses. **Cystic abdominal masses** include hydronephrosis, multicystic-dysplastic kidneys, adrenal hemorrhage, hydrometrocolpos, intestinal duplication, and choledochal, ovarian, omental, or pancreatic cysts. **Solid masses** include neuroblastoma, congenital mesoblastic nephroma, hepatoblastoma, and teratoma. A solid flank mass may be caused by **renal vein thrombosis** , which becomes clinically apparent with hematuria, hypertension, and thrombocytopenia. Renal vein thrombosis in infants is associated with polycythemia, dehydration, maternal diabetes, asphyxia, sepsis, nephrosis, and hypercoagulable states such as antithrombin III and protein C deficiency.

Abdominal distention at birth or shortly afterward suggests either obstruction or perforation of the gastrointestinal tract, often as a result of meconium ileus; later distention suggests lower bowel obstruction, sepsis, or peritonitis. A scaphoid abdomen in a newborn suggests diaphragmatic hernia. Abdominal wall defects produce an **omphalocele** when they occur through the umbilicus and gastroschisis when they occur lateral to the midline (see Chapter 125). Omphaloceles are associated with other anomalies and syndromes, such as Beckwith-Wiedemann, conjoined twins, trisomy 18, meningomyelocele, and imperforate anus. **Omphalitis** is an acute local inflammation of the periumbilical tissue that may extend to the abdominal wall, the peritoneum, the umbilical vein or portal vessels, or the liver and may result in later portal hypertension. The umbilical cord should have 2 arteries and 1 vein. A single umbilical artery is associated with an increased risk for an occult renal anomaly.

Genitals

The genitals and mammary glands normally respond to transplacentally acquired maternal hormones to produce enlargement and secretion of the breasts in both sexes and prominence of the genitals in females, often with considerable nonpurulent discharge. These transitory manifestations require no intervention.

An imperforate hymen or other causes of vaginal obstruction may result in **hydrometrocolpos** and a lower abdominal mass. A normal scrotum at term is relatively large; its size may be increased by the trauma of breech delivery or by a transitory **hydrocele** , which is distinguished from a hernia by palpation and transillumination. The testes should be in the scrotum or should be palpable in the canals in term infants. Black male infants usually have dark pigmentation of the scrotum before the rest of the skin assumes its permanent color. The scrotum may be ecchymotic from breech presentation or a retroperitoneal hemorrhage; it may contain meconium particles associated with meconium peritonitis.

The prepuce or foreskin of a newborn infant is normally tight and adherent to the penile glans at birth and cannot be retracted. The foreskin should separate naturally over several months. Severe **hypospadias** or **epispadias** should always suggest either that abnormal sex chromosomes are present (see Chapter 98) or that the infant is actually a masculinized female with an enlarged clitoris, because this finding may be the first evidence of adrenogenital syndrome (see Chapter 594). Erection of the penis is common and has no significance. Urine is usually passed during or immediately after birth; a period without voiding may normally follow. Most neonates void by 12 hr, and approximately 95% of preterm and term infants void within 24 hr.

Anus

Some passage of **meconium** usually occurs within the 1st 12 hr after birth; 99% of term infants and 95% of premature infants pass meconium within 48 hr of birth. Physical examination is usually sufficient for diagnosis of **imperforate anus** , if the anal opening is absent or incorrectly located. However, if there is a fistula to the skin, urethra or vagina, a newborn can pass meconium; in such cases, unless a careful exam is done, imperforate anus may not be suspected. Abdominal radiographs are used to confirm distal obstruction and to determine how low the rectum is. In females with imperforate anus, careful examination of the vestibule must be made to ensure separate openings of the urethra and vagina. All newborns with anorectal malformations warrant evaluation for possible associated cardiac, renal and spine anomalies.

The dimple or irregularity in skin fold often normally present in the sacrococcygeal midline may be mistaken for an actual or potential neurocutaneous sinus.

Extremities

During examination of the extremities, the effects of fetal posture (see Chapter 692) should be noted so that their cause and usual transitory nature can be explained to the mother. Such explanations are particularly important after breech presentations. A fracture or nerve injury associated with delivery can be detected more frequently by observation of the extremities in spontaneous or stimulated activity than by any other means. The hands and feet should be examined for polydactyly, syndactyly, and abnormal dermatoglyphic patterns such as a simian crease.

The hips of all infants should be examined with specific maneuvers to rule out congenital dislocation (see Chapter 698.1).

Neurologic Examination

See Chapter 21 .

In utero neuromuscular diseases associated with limited fetal motion produce a constellation of signs and symptoms that are independent of the specific disease. Severe positional deformations and contractures produce **arthrogryposis** . Other manifestations of fetal neuromuscular disease include breech presentation, polyhydramnios, failure to breathe at birth, pulmonary hypoplasia, dislocated hips, undescended testes, thin ribs, and clubfoot. Many congenital disorders manifest as hypotonia, hypertonia, or seizures.

113.3

Routine Newborn Care

Neera K. Goyal

The initial steps of management for all newborns after delivery are to provide warmth, drying, and tactile stimulation, while simultaneously evaluating respiratory effort, heart rate, and color. Full-term, vigorous infants may initially be placed on the mother's abdomen after delivery, during which time **delayed clamping** of the umbilical cord (30-60 sec) is recommended to improve transitional circulation and increase neonatal red blood cell (RBC) volume. Clearing the mouth of secretions with gentle suction with a bulb syringe or soft catheter is indicated if there is an excessive (copious) amount of fluid in the mouth or nares. In resource-poor countries, gentle wiping of the face, nose, and mouth with a soft cloth may be equally effective as a bulb syringe. Spontaneously breathing neonates without distress require no assisted method to clear their airway.

The **Apgar score** is a practical method of systematically evaluating infants immediately after birth and is assessed at 1 and 5 min of life (Table 113.2). Most healthy infants who appear to be in satisfactory condition may remain in skin-to-skin contact with their mothers for immediate bonding and nursing. However, infants who fail to initiate or sustain respiratory effort after stimulation, those with a heart rate <100 beats/min, and those with persistent central cyanosis should be placed under warmers for prompt resuscitation and monitoring (see Chapter 121). Apgar scores should not be used to determine need for resuscitation or to guide steps of resuscitation. However, changes in Apgar scores at sequential time points after birth can reflect how well the infant is responding to resuscitation. If the 5 min score remains <7, additional scores should be assigned every 5 min for up to 20 min. In addition to fetal distress, a number of factors, including prematurity and drugs given to the mother during labor, can result in low Apgar scores (Table 113.3).

Table 113.2

Apgar Evaluation of Newborn Infants[*]

SIGN	**0**	**1**	**2**
Heart rate	Absent	Below 100	Over 100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion of extremities	Active motion
Response to catheter in nostril (tested after oropharynx is clear)	No response	Grimace	Cough or sneeze
Color	Blue, pale	Body pink, extremities blue	Completely pink

[*] At 60 sec after complete birth of the infant (disregarding the cord and placenta), the 5 objective signs listed here are evaluated, and each is given a score of 0, 1, or 2. A total score of 10 indicates an infant in the best possible condition. An infant with a score of 0-3 requires immediate resuscitation.

Adapted from Apgar V: A proposal for a new method of evaluation of the newborn infant, *Curr Res Anesth Analg* 32:260–267, 1953.

Table 113.3

Factors Affecting the Apgar Score[*]

FALSE-POSITIVE RESULT [†]
Prematurity
Analgesics, narcotics, sedatives
Magnesium sulfate
Acute cerebral trauma
Precipitous delivery
Congenital myopathy
Congenital neuropathy
Spinal cord trauma
Central nervous system anomaly
Lung anomaly (diaphragmatic hernia)
Airway obstruction (choanal atresia)
Congenital pneumonia and sepsis
Previous episodes of fetal asphyxia (recovered)
Hemorrhage-hypovolemia
FALSE-NEGATIVE RESULT [‡]
Maternal acidosis
High fetal catecholamine levels
Some full-term infants

[*] Regardless of the etiology, a low Apgar score because of fetal asphyxia, immaturity, central nervous system depression, or airway obstruction identifies an infant needing immediate resuscitation.

[†] No fetal acidosis or hypoxia; low Apgar score.

[‡] Acidosis; normal Apgar score.

Maintenance of Body Heat

Newborn infants are at risk for heat loss and hypothermia for several reasons. Relative to body weight, the body surface area (BSA) of a newborn infant is approximately 3 times that of an adult. Generation of body heat depends in large part on body weight, but heat loss depends on BSA. In low-birthweight and preterm infants, the insulating layer of subcutaneous fat is thin. The estimated rate of heat loss in a newborn is approximately 4 times that of an adult. Under the usual delivery room conditions (20-25°C [68-77°F]), an infant's skin temperature falls approximately 0.3°C (0.54°F)/min, and deep body temperature decreases approximately 0.1°C (0.18°F)/min during the period immediately after delivery; these rates generally result in a cumulative loss of 2-3°C (3.6-5.4°F) in deep body temperature (corresponding to a heat loss of approximately 200 kcal/kg). The heat loss occurs by 4 mechanisms: **convection** of heat energy to the cooler surrounding air, **conduction** of heat to the colder materials touching the infant, **heat radiation** from the infant to other nearby cooler objects, and **evaporation** from skin and lungs.

Metabolic acidosis, hypoxemia, hypoglycemia, and increased renal excretion of water and solutes may develop in term infants exposed to cold after birth because of their effort to compensate for heat loss. Heat production is augmented by increasing the metabolic rate and oxygen consumption in part by releasing **norepinephrine** , which results in nonshivering thermogenesis through oxidation of fat, particularly brown fat. In addition, muscular activity may increase. Hypoglycemic or hypoxic infants cannot increase their oxygen consumption when exposed to a cold environment, and their central temperature decreases. After labor and vaginal delivery, many newborn infants have mild to moderate metabolic acidosis, for which they may compensate by hyperventilating, a response that is more difficult for infants with central nervous system (CNS) depression (asphyxia, drugs) and infants exposed to cold stress in the delivery room. Therefore, to reduce heat loss, it is desirable to ensure that infants are dried and either wrapped in blankets or placed with the mother or under radiant warmers. **Skin-to-skin contact** with the mother is the optimal method of maintaining temperature in the stable newborn. Because carrying out resuscitative measures on a covered infant or one enclosed in an incubator is difficult, a radiant heat source should be used to warm the baby during resuscitation.

Antiseptic Skin and Cord Care

Nursery personnel should use alcohol-based solutions or chlorhexidine or iodophor-containing antiseptic soaps for routine handwashing before caring for each infant. Rigid enforcement of hand-to-elbow washing for 2 min in the initial wash and 15-30 sec in subsequent washes is essential for staff and visitors entering the nursery. Careful removal of the amniotic fluid and blood from the skin shortly after birth may reduce the risk of infection with bloodborne agents. For the infant's first bath, the entire skin and cord should be cleansed with warm water or a mild nonmedicated soap solution and rinsed with water to reduce the incidence of skin and periumbilical colonization with pathogenic bacteria and subsequent infectious complications. Based on World Health Organization (WHO) recommendations, this should be delayed until 24 hr of life to allow full transition to extrauterine life with emphasis on maternal–infant bonding and early breastfeeding. To avoid heat loss, the infant should then be dried and wrapped in clean blankets.

Staphylococcus aureus remains the most frequent pathogenic bacteria to colonize the umbilical cord, although other common pathogens include group A and group B streptococci and gram-negative bacilli. Pathogenic bacteria may derive from the mother's birth canal or various bacterial sources, including the nonsterile hands of personnel attending the delivery. Topical chlorhexidine to the umbilical cord is recommended for infants born outside of birthing centers or hospital settings, and for those born in low-resource communities with high neonatal mortality rates. However, in high-resource countries the incidence of omphalitis is very low and the severity is mild, so **dry cord care** is recommended without the application of topical substances such as alcohol or chlorhexidine. Dry cord care involves leaving the umbilical cord exposed to air or loosely covered, cleaning it with soap and water if it becomes soiled. Colonization and infection of newborns from potentially pathogenic organisms can also be reduced through continuous rooming-in with their mother, which creates an environment conducive for colonization from less pathogenic bacteria acquired from the mother's flora.

Vernix is spontaneously shed within 2-3 days, much of it adhering to the clothing, which should be completely changed daily. The diaper should be checked before and after feeding and when the baby cries; it should be changed when wet or soiled. The perineal area can be cleaned with baby wipes or with mild soap and warm water. Meconium or feces should be cleansed from the buttocks with sterile cotton moistened with sterile water. The foreskin of a male infant should not be retracted.

Newborn Prophylaxis and Screening

Newborn assessment and vital sign monitoring may vary by hospital but generally decreases in frequency after the 1st 1-2 hr after birth. For well-appearing newborns, a reasonable interval between assessments is 4 hr during the 1st 2-3 days of life and 8 hr thereafter. The infant's temperature should be taken by axillary measurement, with a normal range of 36.5-37.4°C (97.7-99.3°F). Weighing at birth and daily thereafter is sufficient.

The eyes of all infants, including those of cesarean birth, must be protected against **gonococcal ophthalmia neonatorum** by application of a 1 cm ribbon of erythromycin (0.5%) or tetracycline (1.0%) sterile ophthalmic ointments in each lower conjunctival sac. This procedure may be delayed during the initial short-alert period after birth to promote bonding, but once applied, drops should not be rinsed out (see Chapters 219 and 253.3). A 1% silver nitrate solution is an acceptable alternative but leads to a transient chemical conjunctivitis in 10–20% of cases.

Although hemorrhage in newborn infants can be a result of factors other than vitamin K deficiency, an intramuscular (IM) injection of 0.5-1 mg of water-soluble vitamin K_1 (phytonadione) should be given to all infants shortly after birth to prevent **hemorrhagic disease of the newborn** (see Chapter 124.4). Oral vitamin K is *not* as effective as the parenteral dosage.

Hepatitis B immunization before discharge from the nursery is recommended for newborns with weight >2 kg, irrespective of maternal hepatitis status.

Neonatal screening is available for various genetic, metabolic, hematologic, and endocrine disorders. All states in the United States have adopted the recommendations of the **Advisory Committee on Heritable Disorders in Newborns and Children** , although the specific tests performed vary by state based in part to disease prevalence, detection rates, and costs (see Chapter 102). The most commonly identified disorders (and their rates) include hypothyroidism (52/100,000 births), cystic fibrosis (30/100,000), hemoglobinopathies (26/100,000), medium-chain acyl–coenzyme A dehydrogenase deficiency (6/100,000), galactosemia (5/100,000), phenylketonuria (5/100,000), and adrenal hyperplasia (5/100,000). To be effective in the timely identification and prompt management of treatable diseases, screening programs must include not only high-quality laboratory tests but also follow-up of infants with abnormal test results; education, counseling, and psychologic support for families; and prompt referral of the identified neonate for accurate diagnosis and appropriate treatment.

Hearing impairment , a serious morbidity that affects speech and language development, may be severe in 2/1,000 births and overall affects 5/1,000 births. Universal screening of infants is recommended to ensure early detection of hearing loss and appropriate, timely intervention. Parents of infants who fail screening should be counseled on the importance of screening results, reinforcing the need for prompt audiologic confirmation and emphasizing the potential for normal language development with prompt intervention.

Universal screening with pulse oximetry provides early detection of ductal dependent cyanotic congenital heart disease (see Chapter 452).

Universal screening for hyperbilirubinemia should include risk assessment in all infants with measurement of serum or transcutaneous bilirubin levels before hospital discharge (see Chapter 123.4 , Kernicterus).

Universal screening for congenital hip dysplasia with physical examination with the **Ortolani test** (sensation of the dislocated hip reducing) and **Barlow test** (unstable hip dislocating from the acetabulum) is recommended, but routine hip ultrasound is not indicated.

Screening for hypoglycemia is risk based and should be performed in infants who are small for gestational age, large for gestational age, born to mothers who have diabetes, preterm, or symptomatic (see Chapter 127.1).

For infants with suspected maternal chorioamnionitis, current clinical guidelines recommend laboratory screening for sepsis, including a blood culture, and at least 48 hr of broad-spectrum antibiotic therapy. However, evidence suggests a low incidence of sepsis among well-appearing, term neonates, and that frequent, reliable observation to detect early signs of sepsis, with or without laboratory studies, may be appropriate. (see Chapter 129).

Table 113.4 lists minimum criteria to be met before newborn discharge. A shortened hospital stay (<48 hr after delivery) may be reasonable for healthy, term newborns but is not always appropriate. Early discharge requires careful ambulatory follow-up at home (by a visiting nurse) or in the office within 48 hr of discharge.

Table 113.4

Criteria for Discharge of Healthy Term Newborns*

GENERAL
Normal vital signs including respiratory rate <60 breaths/min; axillary temperature 36.5°C-37.4°C (97.7°-99.3°F) in open crib
Physical examination reveals no abnormalities requiring continued hospitalization
Regular urination; stool × 1
At least 2 uneventful, successful feedings
No excessive bleeding 2 hr after circumcision
LABORATORY AND OTHER SCREENS
Maternal syphilis, hepatitis B surface antigen, and HIV status
Newborn hepatitis B vaccine administered or appointment for vaccination confirmed
Maternal tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis, adsorbed (Tdap) vaccination
Maternal influenza vaccination during flu season
Evaluation and monitoring for sepsis based on maternal risk factors including GBS colonization
Umbilical or newborn direct Coombs test and blood type if clinically indicated
Expanded newborn metabolic screening
Hearing screening
Screening for hypoglycemia based on infant risk factors
Pulse oximetry screening
Screening for hyperbilirubinemia, with management and follow-up as recommended based on level of jaundice
SOCIAL
Evidence of parental knowledge, ability, and confidence to care for the baby at home: Feeding Normal stool and urine output Cord, skin, and genital care Recognition of illness (jaundice, poor feeding, lethargy, fever, etc.) Infant safety (car seat, supine sleep position, etc.)
Availability of family and physician support (physician follow-up)
Assessment of family, environmental, and social risk factors: Substance abuse History of child abuse Domestic violence Mental illness Teen mother Homelessness Barriers to follow-up
Source of continuing medical care is identified.

113.4

Circumcision

Neera K. Goyal

Male circumcision consists of the surgical removal of some, or all, of the foreskin from the penis, and is one of the most common procedures performed worldwide. Circumcision performed during the newborn period has considerably lower complication rates than when performed later in life. The procedure should only be performed in healthy newborns whose condition is stable. Those providing circumcision should be adequately trained in both sterile techniques and effective pain management to reduce risk of complications. The surgery includes dilation of the preputial orifice to visualize the glans, freeing the preputial epithelium from the epithelium of the glans, placement of the circumcision device (Gomco clamp, Plastibell, or Mogen clamp) to enhance hemostasis, and removal of foreskin. For pain management, topical 4% lidocaine (i.e., LMX4 cream), a dorsal penile nerve block, and a subcutaneous ring block are all effective options. Topical anesthetic creams may cause a higher incidence of skin irritation in low-birthweight infants; therefore penile nerve block techniques should be chosen for this group. Usually, the dorsal penile nerve block consists of injections of 0.4 mL of 1% lidocaine *without* epinephrine on both sides of the base of the penis. The subcutaneous **circumferential ring block** involves 0.8 mL of 1% lidocaine *without* epinephrine injected at the base or midshaft of the penis and may provide the most effective analgesia compared with other techniques. Nonpharmacologic techniques, such as positioning on a padded environment and use of sucrose pacifiers, are useful adjuncts to improve infant comfort during the procedure but are insufficient as sole therapies to prevent procedural and postprocedural pain.

Contraindications to this procedure include critically ill infants, those with blood dyscrasias, individuals who have a family history of bleeding disorders, and those who have congenital abnormalities (e.g., hypospadias), congenital chordee, or deficient shaft skin (e.g., penoscrotal fusion, congenital buried penis). In addition, it should be confirmed before the procedure that the newborn received IM vitamin K in accordance with standard practice of newborn care. Premature infants may undergo circumcision before discharge.

Preventive health benefits of elective circumcision for male newborns include significant reductions in the risk of urinary tract infection in the 1st year of life, heterosexual acquisition of HIV and transmission of other sexually transmitted infections (human papillomavirus, herpes simplex virus type 2, and syphilis), and penile cancer. Acute complications from circumcision in the United States and other high-resource countries are rare, including bleeding (0.08–0.18%), infection (0.06%), and penile injury (0.04%). More catastrophic injuries, including glans or penile amputation, are extremely rare and published as case reports only. Later complications can include excessive residual skin (incomplete circumcision), excessive skin removal, adhesions (natural and vascularized skin bridges), meatal stenosis, phimosis, and epithelial inclusion cysts.

Current evidence indicates while health benefits outweigh the risks of male circumcision, health benefits are not great enough to recommend routine circumcision for all male newborns. Therefore, physicians who counsel families about this decision should explain the potential benefits and risks, in a nonbiased manner, and ensure that parents understand that circumcision is an elective procedure. Ultimately, parents should decide whether circumcision is in the best interests of their male child, weighing the medical information in context of their own religious, ethical, and cultural beliefs and practices.

Regardless of whether or not the newborn is circumcised, parents should be instructed in the care of the penis at discharge from the newborn hospital stay. The circumcised penis should be washed gently each day with soap and water. As part of normal healing, the glans may appear raw or yellowish for 7-10 days. Gauze with petroleum jelly can be used to cover the area and should be changed with each urine and stool until the glans heals.

113.5

Parent–Infant Bonding

Neera K. Goyal

See also Chapter 21 .

Normal infant development depends partly on a series of affectionate responses exchanged between a mother and her newborn infant that binds them psychologically and physiologically. This bonding is facilitated and reinforced by the emotional support of a loving family. The attachment process may be important in enabling some mothers to provide loving care during the neonatal period and subsequently during childhood. The power of this attachment is so great that it enables the mother and the father to make unusual sacrifices necessary for the day-to-day care of the infant, care night after night, giving feedings 24 hr a day, attending to crying, and so on. The sacrifices continue for many years as parents dedicate much of their lives to their children.

Parent–infant bonding is initiated before birth with the planning and confirmation of the pregnancy. Subsequently, there is a growing awareness of the baby as an individual, starting usually with the remarkably powerful event of quickening or sensation of fetal movements. After delivery and during the ensuing weeks, sensory (visual, auditory, olfactory) and physical contact between the mother and baby triggers various mutually rewarding and pleasurable interactions, such as the mother touching the infant's extremities and face with her fingertips and encompassing and gently massaging the infant's trunk with her hands. Touching an infant's cheek elicits responsive turning toward the mother's face or toward the breast with nuzzling and licking of the nipple, a powerful stimulus for prolactin secretion. An infant's initial quiet alert state provides the opportunity for eye-to-eye contact, which is particularly important in stimulating the loving and possessive feelings of many parents for their babies. An infant's crying elicits the maternal response of touching the infant and speaking in a soft, soothing, higher-toned voice.

Initial contact between the mother and infant should take place in the delivery room, and opportunities for extended intimate contact and breastfeeding should be provided within the 1st hours after birth. Delayed or abnormal maternal–infant bonding, as occurs because of prematurity, infant or maternal illness, birth defects, or family stress, may harm infant development and maternal caretaking ability. Hospital routines should be designed to encourage parent–infant contact. Rooming-in arrangements, care by parents, and family-centered care increase the opportunities for better parent–infant interaction.

Rooming-in and Breastfeeding

See Chapter 56 for full discussions of breastfeeding and formula feeding.

Ample evidence indicates that there are infant and maternal benefits to breastfeeding. One important hospital practice to encourage successful breastfeeding is rooming-in of newborns with their mothers. Therefore, it should be encouraged that term, healthy infants remain continuously in the mother's room whenever possible. To reduce the risk of **sudden infant death syndrome** , infants should be placed to sleep supine in a bassinet, preferably of clear plastic to allow for easy visibility and care. All professional care should be given to the infant in the bassinet, including the physical examination, clothing changes, temperature taking, skin cleansing, and other procedures that, if performed elsewhere, would establish a common contact point and possibly provide a channel for cross-infection. The clothing and bedding should be minimal, only enough needed for an infant's comfort; the room temperature should be kept at approximately 22-26°C (72-78°F).

Additional practices that encourage successful breastfeeding include antepartum education and encouragement, immediate postpartum mother–infant contact with suckling, demand feeding, inclusion of maternal partners in breastfeeding education, and support from experienced women. Nursing at first for least 5 min at each breast is reasonable, allows a baby to obtain most of the available breast contents, and provides effective stimulation for increasing the milk supply. Nursing episodes should then be extended according to the comfort and desire of the mother and infant. A confident and relaxed mother, supported by an encouraging home and hospital environment, is likely to nurse well. The **Baby-Friendly Hospital Initiative** , a global effort sponsored by WHO and the UN Children's Fund to promote breastfeeding, recommends 10 steps to successful breastfeeding (Table 113.5). When instituted together as a complete bundle, these practices can improve multiple outcomes, including breastfeeding initiation, duration of exclusive breastfeeding, and duration of overall breastfeeding. In the United States, however, the vast majority of newborns are still not delivered in Baby-Friendly hospitals that have implemented all 10 steps. Educating mothers during pregnancy and showing mothers how to breastfeed are the most widely implemented strategies, while establishment of written breastfeeding policies, restriction of formula access, and establishment of breastfeeding support groups after discharge are among the most challenging to implement.

Table 113.5

Ten Steps to Successful Breastfeeding

Every facility providing maternity services and care for newborn infants should accomplish the following:

1. Have a written feeding policy that is routinely communicated to staff and patients, comply with WHO restrictions on marketing of breast milk substitutes, and establish ongoing monitoring and data-management systems.
2. Ensure that staff have sufficient knowledge, competence, and skills to support breastfeeding.
3. Discuss the importance and management of breastfeeding with pregnant women and their families.
4. Facilitate immediate and uninterrupted skin-to-skin contact and help initiate breastfeeding as soon as possible after birth.
5. Support mothers to initiate and maintain breastfeeding and manage common difficulties.
6. Give newborn infants no food or drink other than breast milk unless *medically* indicated.
7. Practice rooming-in (allow mothers and infants to remain together) 24 hr a day.
8. Support mothers to recognize and respond to their infants' feeding cues.
9. Counsel mothers on the use and risks of feeding bottles, teats, and pacifiers.
10. Coordinate discharge to ensure timely access to ongoing support and care.

Adapted from Guideline: Protecting, promoting and supporting breastfeeding in facilities providing maternity and newborn services. Geneva, 2017, World Health Organization.

Drugs and Breastfeeding

Ideally, drugs of any type should be avoided in breastfeeding women, unless prescribed for specific medical conditions. Many mothers are advised to discontinue breastfeeding or avoid taking essential medications due to fears of adverse infant effects. However, such an approach may be inappropriate in many cases, as only a small proportion of medications are contraindicated when breastfeeding. When weighing risks and benefits, healthcare providers should consider the following factors in discussion with the family: maternal need for the medication, potential effects on lactation, extent of excretion into human milk, extent of oral absorption by the breastfeeding infant, potential adverse infant effects, proportion of feedings comprised of breast milk, and age of the infant. Although previous editions of this text sought to list medications potentially used during lactation and to describe their potential for infant harm, revisions to this text can no longer keep pace with rapidly changing information available via the internet, published studies, and new drug approvals. For up-to-date information on drug levels in human milk and infant serum, possible adverse effects on infant health and lactation, and recommendations for possible medication alternatives, providers should refer to LactMed (http://toxnet.nlm.nih.gov).

Among US women of childbearing age, illicit drug use and legal substance use or abuse is common, with >5% of pregnant women reporting active illicit drugs, >9% alcohol use, and >15% cigarette use. Multiple drug use is also common. For mothers desiring to breastfeed with a history of current or past illegal drug abuse or legal drug use or abuse, healthcare providers must carefully and thoughtfully weigh the documented benefits of human milk and breastfeeding against the risks associated with the substance that the infant may be exposed to during lactation. Most illicit drugs are found in human milk with varying degrees of oral bioavailability, and breastfeeding is generally contraindicated (Table 113.6). However, mothers with substance use disorders should be encouraged to breastfeed under the following circumstances: established engagement in substance abuse treatment (e.g., methadone or buprenorphine maintenance therapy) that includes counseling and social support; abstinence from drug use for 90 days before delivery, with maternal urine toxicology testing at delivery negative other than prescribed substances, ability to maintain sobriety demonstrated in an outpatient setting, and engagement and compliance with care.

Table 113.6

Drugs of Abuse and Adverse Infant Effects

CONTRAINDICATED
Amphetamines
Antineoplastic agents
Bromocriptine
Chloramphenicol
Clozapine
Cocaine
Cyclophosphamide
Doxorubicin
Ecstasy (MDMA)
Ergots
Gold salts
Heroin
Immunosuppressants
Methamphetamine
Phencyclidine (PCP)
Radiopharmaceuticals
Thiouracil
USE WITH CAUTION
Alcohol
Amiodarone
Anthraquinones (laxatives)
Aspirin (salicylates)
Atropine
β-Adrenergic blocking agents
Benzodiazepines
Birth control pills
Bromides
Cascara
Codeine
Dicumarol
Dihydrotachysterol
Domperidone
Estrogens
Hydrocodone
Lithium
Marijuana
Metoclopramide
Meperidine
Oxycodone
Phenobarbital[*]
Primidone
Reserpine
Salicylazosulfapyridine (sulfasalazine)

[*] Watch for sedation.

Contraindications to Breastfeeding

Medical contraindications to breastfeeding in the United States include infants with galactosemia, maple syrup urine disease, and phenylketonuria. Maternal conditions that contraindicate breastfeeding include infection with human T-cell lymphotropic virus types 1 and 2, active tuberculosis (until appropriately treated ≥2 wk and not considered contagious), herpesvirus infection on breast, use of or dependence on certain illicit drugs, and maternal treatment with some radioactive compounds (Table 113.7). Because clean water and affordable replacement feeding are available in the United States, it is recommended that HIV-infected mothers not breastfeed their infants regardless of maternal viral load and antiretroviral therapy. However, in resource-limited countries where diarrhea and pneumonia are significant causes of infant and child mortality, breastfeeding may not be contraindicated for HIV-positive mothers receiving antiretroviral therapy. Donor human milk, particularly that purchased online, may be contaminated with potential pathogens. Contamination is much less of a concern with pasteurized human milk obtained from a milk bank.

Table 113.7

Summary of Infectious Agents Detected in Milk and Newborn Disease

INFECTIOUS AGENT	DETECTED IN BREAST MILK?	BREAST MILK REPORTED AS CAUSE OF NEWBORN DISEASE?	MATERNAL INFECTION CONTRAINDICATION TO BREASTFEEDING?
BACTERIA			
Mastitis/*Staphylococcus aureus*	Yes	No	No, unless breast abscess present
Mycobacterium tuberculosis :			
Active disease	Yes	No	Yes, because of aerosol spread, or tuberculosis mastitis
Purified protein derivative skin test result positive, chest radiograph findings negative	No	No	No
Escherichia coli , other gram-negative rods	Yes, stored	Yes, stored	—
Group B streptococci	Yes	Yes	No*
Listeria monocytogenes	Yes	Yes	No*
Coxiella burnetii	Yes	Yes	No*
Syphilis	No	No	No †
VIRUSES			
HIV	Yes	Yes	Yes, developed countries
Cytomegalovirus:			
Term infant	Yes	Yes	No

Preterm infant	Yes	Yes	Evaluate on an individual basis
Hepatitis B virus	Yes, surface antigen	No	No, developed countries [‡]
Hepatitis C virus	Yes	No	No [§]
Hepatitis E virus	Yes	No	No
Human T-cell leukemia virus (HTLV)-1	Yes	Yes	Yes, developed countries
HTLV-2	Yes	Uncertain	Yes, developed countries
Herpes simplex virus	Yes	Yes	No, unless breast vesicles present
Rubella			
Wild type	Yes	Yes, rare	No
Vaccine	Yes	No	No
Varicella-zoster virus	Yes	No	No, cover active lesions [¶]
Epstein-Barr virus	Yes	No	No
Human herpesvirus (HHV)-6	No	No	No
HHV-7	Yes	No	No
West Nile virus	Possible	Possible	Unknown
Zika virus	Yes	No	No
PARASITES			
Toxoplasma gondii	Yes	Yes, 1 case	No

[*] Provided that the mother and child are taking appropriate antibiotics.

[†] Treat mother and child if active disease.

[‡] Immunize and immune globulin at birth.

[§] Provided that the mother is HIV seronegative. Mothers should be counseled that breast milk transmission of hepatitis C virus has not been documented, but is theoretically possible.

[¶] Provide appropriate antivaricella therapy or prophylaxis to newborn.

CHAPTER 114

High-Risk Pregnancies

Kristen R. Suhrie, Sammy M. Tabbah

The care of high-risk pregnancies should be coordinated with an experienced maternal-fetal medicine specialist.

In general, high-risk pregnancies are those that increase the likelihood of maternal complications, miscarriage, fetal death, preterm delivery, intrauterine growth restriction (IUGR), poor cardiopulmonary or metabolic transitioning at birth, fetal or neonatal disease, congenital malformations, or intellectual impairment and other handicaps (Table 114.1).There is no accepted comprehensive definition of what constitutes a *high-risk pregnancy* , therefore, specific epidemiologic data regarding the incidence/prevalence cannot be reliably reported. Some factors, such as ingestion of a teratogenic drug in the first trimester, are causally related to the risk, while others, such as polyhydramnios, are associations that alert a physician to determine the etiology and avoid the inherent risks associated with excessive amniotic fluid. Although assessing antepartum risk is important in reducing perinatal mortality and morbidity, some pregnancies become high risk only during labor and delivery; therefore careful monitoring is critical throughout the intrapartum course.

Table 114.1

Factors Associated With High-Risk Pregnancy

ECONOMIC
Poverty
Unemployment
Uninsured, underinsured
Poor access to prenatal care
CULTURAL/BEHAVIORAL
Low educational status
Poor healthcare attitudes

No care or inadequate prenatal care
Cigarette, alcohol, or illicit drug use
Age <20 or >40 yr
Unmarried
Short interpregnancy interval (<18 mo between pregnancies)
Lack of support group (husband, family, religion)
Stress (physical, psychologic)
Black race (preterm birth rates are 48% higher than for other women)
BIOLOGIC/GENETIC
Previous low-birthweight or preterm infant
Low weight for height
Poor weight gain during pregnancy
Short stature
Poor nutrition
Consanguinity
Intergenerational effects
Low maternal birthweight
Maternal obesity
Hereditary diseases (inborn error of metabolism)
REPRODUCTIVE
Previous cesarean birth
Previous infertility
Conception by reproductive technology
Prolonged gestation (>40 wk)
Prolonged labor
Previous infant with cerebral palsy, intellectual impairment, birth trauma, or congenital anomalies
Abnormal lie (breech)
Multiple gestations
Premature rupture of membranes
Infection (systemic, amniotic, extra-amniotic, cervical)
Preeclampsia or eclampsia
Uterine bleeding (abruptio placentae, placenta previa)
Parity (0 or >5 previous deliveries)
Uterine or cervical anomalies
Fetal disease
Abnormal fetal growth
Idiopathic premature labor
Iatrogenic prematurity
High or low levels of maternal serum α-fetoprotein
MEDICAL
Diabetes mellitus
Hypertension
Congenital heart disease
Autoimmune disease
Sickle cell anemia
Intercurrent surgery or trauma
Sexually transmitted infection
Maternal hypercoagulable states
Exposure to prescription medications
TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) infection

Identifying high-risk pregnancies is important not only because it is the first step toward prevention but also because critical steps may often be taken to reduce the risks to the fetus or neonate if the physician is alerted to the specific condition early in pregnancy.

Genetic Factors

The occurrence of chromosomal abnormalities, congenital anomalies, inborn errors of metabolism, cognitive delay, or any familial disease in blood relatives increases the risk of the same condition in the infant. Because many parents recognize only obvious clinical manifestations of genetically determined diseases, specific inquiry should be made about any disease affecting one or more blood relatives. A high index of suspicion should be maintained to the possibility of autosomal recessive disorders in offspring of couples who are closely related (i.e., consanguinity).

Maternal Factors

The lowest neonatal mortality rate occurs in infants of mothers who receive adequate prenatal care and who are 20-30 yr of age. Pregnancies in both teenagers and women older than 40, particularly primiparous women, are at increased risk for IUGR, fetal distress, preeclampsia, and stillbirth. Advanced maternal age increases the risk of both chromosomal and nonchromosomal fetal malformations (Fig. 114.1).

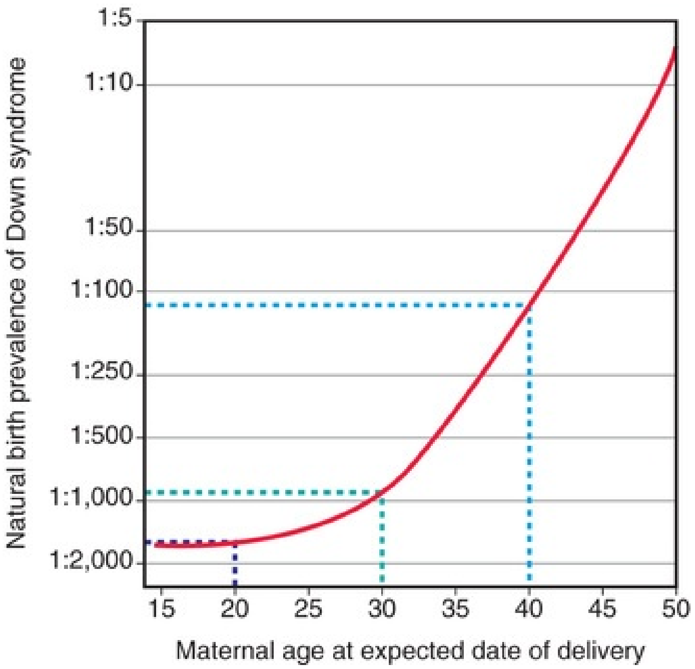

FIG. 114.1 **Natural birth prevalence of Down syndrome according to maternal age. (From Wald NJ, Leck I: *Antenatal and neonatal screening,* ed 2, Oxford, 2000, Oxford University Press.)**

Maternal illness (Table 114.2), multiple pregnancies (particularly those involving monochorionic twins), infections (Table 114.3), and certain drugs (see Chapter 115.4) increase the risk for the fetus. The use of assisted reproductive technology (e.g., ovulation induction, in vitro fertilization, intracytoplasmic sperm injection) increases the risk of prematurity, perinatal mortality, infant morbidity, low and very-low birthweight, imprinting disorders, and cerebral palsy. These risks are largely because of the increase in *multiple gestations* with such technology and the association with *prematurity* . The risks for *birth defects* are also increased with assisted reproductive technology, in part because of epigenetic effects on gene expression.

Table 114.2

Maternal Conditions Affecting the Fetus or Neonate

DISORDER	EFFECT(S)	MECHANISM(S)
Assisted reproductive technology	Beckwith-Wiedemann, Silver-Russel, Angelman syndromes	Altered imprinting
Autoantibody against folate receptors	Neural tube defects	Blockage of cellular uptake of folate
Cervical neoplasia	Preterm premature rupture of membranes, preterm birth	Associated with loop electrosurgical excision procedure or cone therapy

Cholestasis	Preterm delivery, intrauterine fetal demise	Unknown, possibly bile acid–induced fetal arrhythmia
Cyanotic heart disease	IUGR	Low fetal oxygen delivery
Diabetes mellitus:		
Mild	LGA, hypoglycemia	Fetal hyperglycemia: produces hyperinsulinemia; insulin promotes growth
Severe	Growth restriction	Vascular disease, placental insufficiency
Drug addiction	IUGR, neonatal withdrawal	Direct drug effect plus poor nutrition
Endemic goiter	Hypothyroidism	Iodine deficiency
Graves' disease	Transient neonatal thyrotoxicosis	Transplacental passage of IgG thyroid-stimulating antibody
Herpes gestationis (noninfectious)	Bullous rash, intrauterine fetal demise	Autoantibody similar to that in bullous pemphigoid
Hyperparathyroidism	Neonatal hypocalcemia	Maternal calcium crosses to fetus and suppresses fetal parathyroid gland
Hypertension	IUGR, intrauterine fetal demise	Placental insufficiency, fetal hypoxia
Idiopathic thrombocytopenic purpura	Thrombocytopenia	Nonspecific maternal platelet antibodies cross placenta
Isoimmune neutropenia or thrombocytopenia	Neutropenia or thrombocytopenia	Specific antifetus neutrophil or platelet antibody crosses placenta after sensitization of mother
Malignant melanoma	Placental or fetal tumor	Placental metastasis
Myasthenia gravis	Transient neonatal myasthenia	IgG antibody to acetylcholine receptor crosses placenta
Myotonic dystrophy	Neonatal myotonic dystrophy, congenital contractures, respiratory insufficiency	Genetic anticipation
NMDAR antibody encephalitis	Cortical dysplasia	Transplacental antibody
Obesity	LGA or IUGR, hypoglycemia	Unknown, similarities to diabetes
Phenylketonuria	Microcephaly, retardation	Elevated fetal phenylalanine values
Poor nutrition	IUGR, adult insulin resistance	Reduced fetal nutrients, nutritional programming
Preeclampsia, eclampsia	IUGR, thrombocytopenia, neutropenia, fetal demise	Uteroplacental insufficiency, fetal hypoxia, vasoconstriction
Renal transplantation	IUGR	Uteroplacental insufficiency
Rhesus or other blood group sensitization	Fetal anemia, hypoalbuminemia, hydrops, neonatal jaundice	IgG crosses placenta and is directed to fetal cells with antigen
Sickle cell anemia	Preterm birth, IUGR, stillbirth	Placental insufficiency via maternal sickling, producing fetal hypoxia
Systemic lupus erythematosus	Congenital heart block, rash, anemia, thrombocytopenia, neutropenia	Antibody directed to fetal heart, red and white blood cells, and platelets

IgG, Immunoglobulin G; LGA, large for gestational age; NMDAR, antibody to *N* -methyl-D -aspartate receptor; IUGR, intrauterine growth restriction.

Table 114.3

Maternal Infections Affecting the Fetus or Newborn

INFECTION	**MODE(S) OF**	**NEONATAL OUTCOME**

	TRANSMISSION	
BACTERIA		
Group B streptococcus	Ascending cervical	Sepsis, pneumonia
Escherichia coli	Ascending cervical	Sepsis, pneumonia
Listeria monocytogenes	Transplacental	Sepsis, pneumonia
Mycoplasma hominis	Ascending cervical	Pneumonia
Chlamydia trachomatis	Vaginal passage	Conjunctivitis, pneumonia
Syphilis	Transplacental, vaginal passage	Congenital syphilis
Neisseria gonorrhoeae	Vaginal passage	Ophthalmia (conjunctivitis), sepsis, meningitis
Mycobacterium tuberculosis	Transplacental	Prematurity, fetal demise, congenital tuberculosis
VIRUS		
Rubella	Transplacental	Congenital rubella
Cytomegalovirus	Transplacental, breast milk (rare)	Congenital cytomegalovirus or asymptomatic
HIV	Transplacental, vaginal passage, breast milk	Congenital or acquired immunodeficiency syndrome
Hepatitis B	Vaginal passage, transplacental, breast milk	Neonatal hepatitis, chronic hepatitis B surface antigen carrier state
Hepatitis C	Transplacental and vaginal passage	Rarely neonatal hepatitis, ~5% chronic carrier state possible
Herpes simplex type 2 or 1	Intrapartum exposure	Neonatal herpes simplex virus
		Neonatal encephalitis; disseminated viremia, or cutaneous infection
Varicella-zoster	Transplacental:	
	Early	Congenital anomalies
	Late	Neonatal varicella
Parvovirus	Transplacental	Fetal anemia, hydrops
Coxsackievirus B	Fecal-oral	Myocarditis, meningitis, hepatitis
Rubeola	Transplacental	Abortion, fetal measles
West Nile	Transplacental (rare) Possible perinatal	Uncertain, possible rash, encephalitis
Zika	Transplacental	Congenital microcephaly, intracranial calcifications, brain abnormalities, retinal lesions
Chikungunya	Transplacental (rare), perinatal	Neonatal encephalitis
Dengue	Transplacental, perinatal	Neonatal sepsis-like symptoms
PARASITES		
Toxoplasmosis	Transplacental	Congenital toxoplasmosis
Malaria	Transplacental	Abortion, prematurity, intrauterine growth restriction
FUNGI		
Candida	Ascending, cervical	Sepsis, pneumonia, rash

Preterm birth is common in high-risk pregnancies (see Chapter 117). Factors associated with prematurity (see Table 114.1) include multiple gestations as well as biologic markers such as cervical shortening, genital infection, presence of fetal fibronectin in cervicovaginal secretions, serum α-fetoprotein (AFP), and premature rupture of membranes (PROM). PROM occurs in 3% of all pregnancies in the United States and is a leading identifiable cause of prematurity.

The presence of **polyhydramnios** or **oligohydramnios** indicates high-risk pregnancies. Amniotic fluid volume is variable throughout pregnancy and progressively increases from 10 to 30 wk of gestation. On average, volume is typically <10 mL at 8 wk and increases to 630 and 770 mL at 22 and 28 wk, respectively. After 30 wk, the rate of increase slows and the volume remains fairly constant until 36-38 wk gestation. This is followed by a progressive decline, with an average volume of 515 mL at 41 wk of gestation. Polyhydramnios complicates 1–3%, and oligohydramnios 1–5%, of pregnancies; although the true incidence of amniotic fluid disorders is confounded by the lack of a uniform approach to diagnosis. The ultrasound (US) criteria for these diagnoses are based on either the *amniotic fluid index* (AFI) or a *deepest vertical pocket* (DVP). The AFI is determined by measuring the vertical dimension of amniotic fluid pockets in 4 quadrants and reporting the sum of these values. An index >24 cm suggests polyhydramnios, whereas an index <5 cm suggests oligohydramnios. The DVP method reports the deepest pocket of fluid identified with a value of 2-8 cm is considered normal.

Polyhydramnios is associated with preterm labor, abruptio placentae, maternal diabetes, multiple congenital anomalies, aneuploidy, and fetal neuromuscular dysfunction or obstruction of the gastrointestinal tract that interferes with reabsorption of the amniotic fluid that is normally swallowed by the fetus (Table 114.4). Increased fetal urination, as with congenital nephrotic syndrome, or edema formation, such as hydrops fetalis, is also associated with excessive amniotic fluid volume. US demonstrates the increased amniotic fluid surrounding the fetus and detects associated fetal anomalies, hydrops, pleural effusions, and ascites. **Idiopathic** polyhydramnios is the most common cause, affecting approximately 40% of patients. About 25% of these cases will demonstrate an abnormality in the postnatal period. Otherwise, approximately 33% of prenatally detected cases have an associated anomaly, and 25% are associated with maternal diabetes. Severe and symptomatic polyhydramnios may be managed by serial reduction amniocenteses. Treatment is indicated for acute maternal respiratory discomfort and threatened preterm labor, or to provide time for the administration of corticosteroids to enhance fetal lung maturity.

Table 114.4

Conditions Associated With Disorders of Amniotic Fluid Volume

OLIGOHYDRAMNIOS
Amniotic fluid leak/rupture of membranes
Intrauterine growth restriction
Fetal anomalies (particularly GU abnormalities)
Twin-twin transfusion (donor)
Fetal akinesia syndrome
Prune-belly syndrome
Pulmonary hypoplasia
Amnion nodosum
Indomethacin
Angiotensin-converting enzyme inhibitors or receptor antagonists
POLYHYDRAMNIOS
Congenital Anomalies
CNS abnormalities
Tracheoesophageal fistula
Intestinal atresia
Spina bifida
Cleft lip or palate
Cystic adenomatoid lung malformation
Diaphragmatic hernia
Syndromes
Achondroplasia
Klippel-Feil
Trisomy 18
Trisomy 21
TORCH*
Hydrops fetalis
Multiple congenital anomalies
Bartter

Twin-twin transfusion (recipient)
Fetal anemia
Fetal heart failure
Polyuric renal disease (congenital nephrotic syndrome)
Neuromuscular diseases
Nonimmune hydrops
Chylothorax
Teratoma
Idiopathic

* Toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex.

CNS, Central nervous system; GU, genitourinary.

Oligohydramnios is associated with congenital anomalies; IUGR; severe renal, bladder, or urethral anomalies; and drugs that interfere with fetal urination (see Table 114.4). Oligohydramnios becomes most evident after 16-20 wk of gestation, when fetal urination is the major source of amniotic fluid. PROM is a common cause of oligohydramnios and must be ruled out if present, especially if a normal-sized bladder and kidneys are seen on fetal US. Oligohydramnios causes fetal compression abnormalities such as fetal distress/stillbirth from umbilical cord compression, clubfoot, spadelike hands, and a flattened nasal bridge. The most serious complication of chronic oligohydramnios is **pulmonary hypoplasia** , especially if present during the canalicular stage of fetal lung development, which occurs between 16 and 24 wk of gestation. The risk of umbilical cord compression during labor and delivery is increased in pregnancies complicated by oligohydramnios and may be alleviated by saline amnioinfusion via a transcervical intrauterine pressure catheter, which has been demonstrated to reduce the need for cesarean section and improve Apgar scores.

A pregnancy should be considered high risk when the uterus is inappropriately large or small. A uterus large for the estimated stage of gestation suggests the presence of multiple fetuses, polyhydramnios, or an excessively large infant. An inappropriately small uterus suggests oligohydramnios or poor fetal growth.

Mode of delivery is influenced by a complex interplay between maternal-fetal factors. Spontaneous vaginal delivery is always preferred when not otherwise contraindicated. Operative vaginal delivery with vacuum or forceps is a safe alternative to cesarean delivery in appropriately selected patients. The absolute rate of significant newborn injury from these procedures is low, with rates ranging from 1 in 650-850 for **intracranial hemorrhage** and 1 in 220-385 for **neurologic complications** . With some of these injuries, the *indication* for operative vaginal delivery is more likely to be associated with the injury than the procedure itself, and could not have been prevented with a cesarean birth.

Cesarean delivery is indicated for a wide variety of circumstances. Cesarean-born infants present problems that are often related to the unfavorable obstetric circumstance that necessitated the operation. In normal term pregnancies without indication of fetal distress, cesarean delivery carries a greater neonatal risk than delivery through the birth canal. Even when accounting for gestational age, any malformations, birthweight, and multiple gestations, infants born ≥34 wk of gestation via elective cesarean section have 2 times the mortality rate of babies born following a planned vaginal birth, even if cesarean delivery was ultimately required. They also are 1.4 times as likely to require neonatal intensive care unit (NICU) admission and 1.8 times as likely to require breathing support for >30 min after birth. Cesarean-born infants are also at increased risk for persistent **pulmonary hypertension of the newborn** . An elective cesarean birth should be delayed until ≥39 wk of gestation, assuming there is no indication for delivery earlier.

Obstetric anesthesia is a vital component of care on the labor and delivery unit. The most common form of anesthesia in this patient population is *regional* (i.e., epidural or spinal). From the fetal/neonatal standpoint, the most significant complication encountered with this procedure is acute maternal hypotension, which can significantly impair uteroplacental perfusion. Fetal heart rate (FHR) abnormalities are common in this circumstance and, rarely, require emergent cesarean delivery if not amenable to standard in utero resuscitative efforts. *Opioid analgesia* is sometimes used in women who are not candidates for regional anesthesia. This form of pain relief is best avoided as delivery approaches, to minimize risk of neonatal depression. To this end, when opioid use is necessary, it is best to prescribe regimens that have a very short half-life. It is essential that the pediatric team is present at the birth in women receiving opioid analgesia. Furthermore, the pediatricians must be alerted to the specific type of opioid used, because all these drugs cross the placenta and have varying neonatal pharmacokinetics. Some of the common regimens used and their respective neonatal half-life are listed in the referenced American College of Obstetricians and Gynecologists (ACOG) practice bulletin on obstetric anesthesia.

CHAPTER 115

The Fetus

Kristen R. Suhrie, Sammy M. Tabbah

The major emphasis in fetal medicine involves (1) assessment of fetal growth and maturity, (2) evaluation of fetal well-being or distress, (3) assessment of the effects of maternal disease on the fetus, (4) evaluation of the effects of drugs administered to the mother on the fetus, and (5) identification and when possible treatment of fetal disease or anomalies.

One of the most important tools used to access fetal well-being is ultrasonography (ultrasound, US); it is both safe and reasonably accurate. Indications for antenatal US include estimation of gestational age (unknown dates, discrepancy between uterine size and dates, or suspected growth restriction), assessment of amniotic fluid volume, estimation of fetal weight and growth, determination of the location of the placenta and the number and position of fetuses, and identification of congenital anomalies. Fetal MRI is a more advanced imaging method that is thought to be safe to the fetus and neonate and is used for more advanced diagnostic and therapeutic planning (Fig. 115.1).

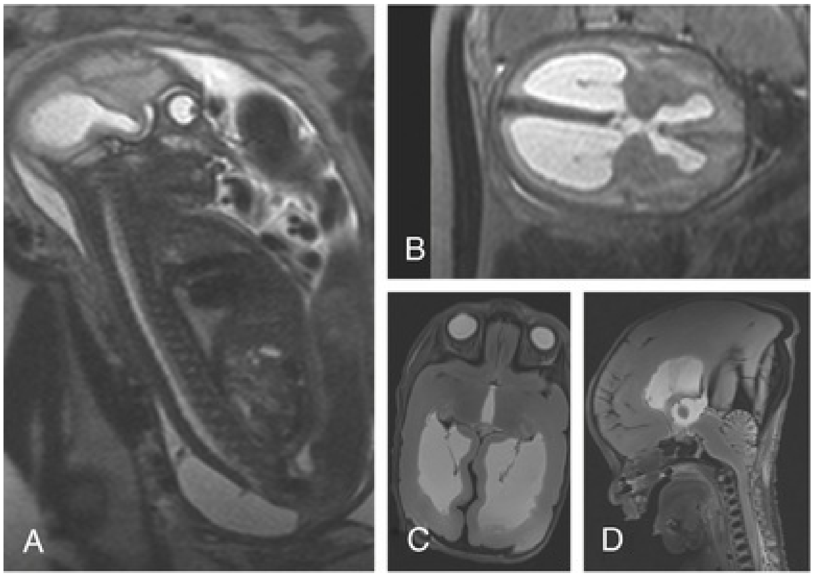

FIG. 115.1 MRI of fetal pathology. A, Fetus with sacral myelomeningocele at 30 wk gestation. B, Ventriculomegaly in the same fetus as in A. C, MRI can also be used for postmortem examination, here in a 33 wk old fetus, demonstrating ventriculomegaly with heterotopic foci in the ventricular walls. D, Chiari II malformation of the brainstem. (Courtesy of Filip Claus, Aalst, Belgium.)

115.1

Fetal Growth and Maturity

Kristen R. Suhrie, Sammy M. Tabbah

Fetal growth can be assessed by US as early as 6-8 wk of gestation by measurement of the crown-rump length. Accurate determination of gestational age can be achieved through the 1st half of pregnancy; however, first-trimester assessment by crown-rump length measurement is the most effective method of pregnancy dating. In the second trimester and beyond, a combination of biometric measures (i.e., biparietal diameter, head and abdominal circumference, femoral diaphysis length) is used for gestational age and growth assessment (Fig. 115.2). If a single US examination is performed, the most information can be obtained with a scan at 18-20 wk, when both gestational age and fetal anatomy can be evaluated. Serial scans assessing fetal growth are performed when risk factors for **fetal growth restriction (FGR)** are present. Two patterns of FGR have been identified: *symmetric* FGR, typically present early in pregnancy, and *asymmetric* FGR, typically occurring later in gestation. The most widely accepted definition of FGR in the United States is an **estimated fetal weight (EFW)** of less than the 10th percentile (Fig. 115.3). Some aspects of human fetal growth and development are summarized in Chapter 20 .

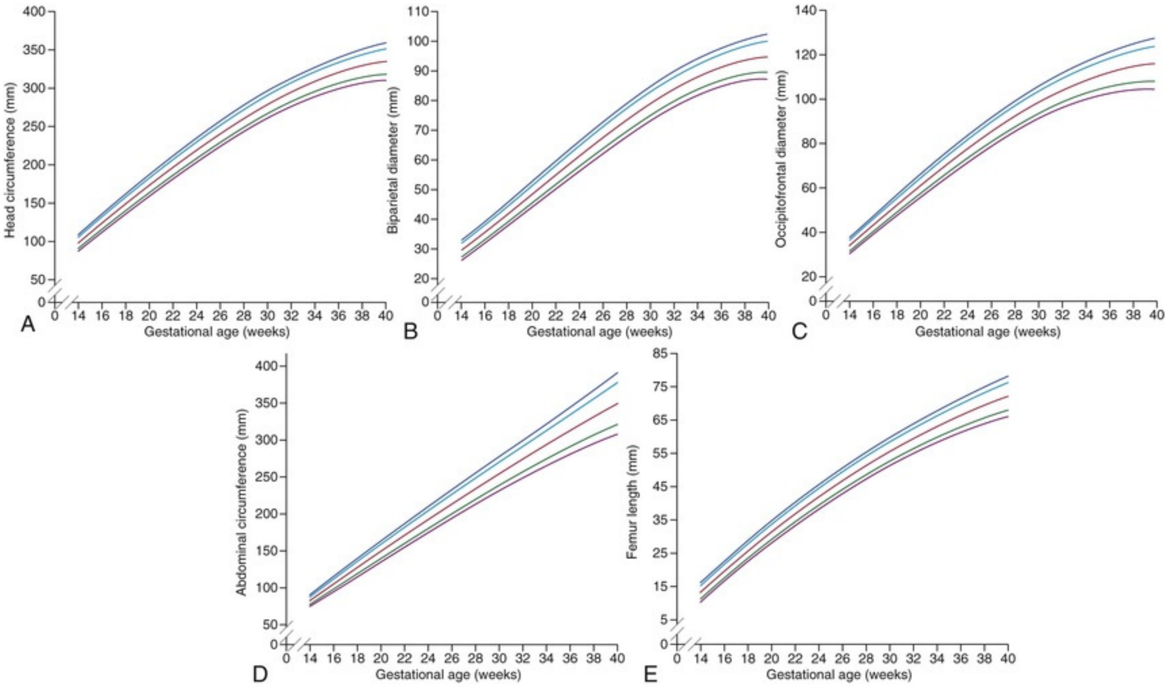

FIG. 115.2 Fetal measurements: 3rd, 10th, 50th, 90th, and 97th smoothed centile curves. A, Fetal head circumference; B, fetal biparietal diameter; C, fetal occipitofrontal diameter; D, fetal abdominal circumference; and E, fetal femur length measured by ultrasound (US) according to gestational age. (From Papageorghiou AT, Ohyma EO, Altman DG, et al: International standards for fetal growth based on serial US measurements: the Fetal Growth Longitudinal Study of the INTERGROWTH-21st Project, Lancet 384:869–878, 2014, Fig 3.)

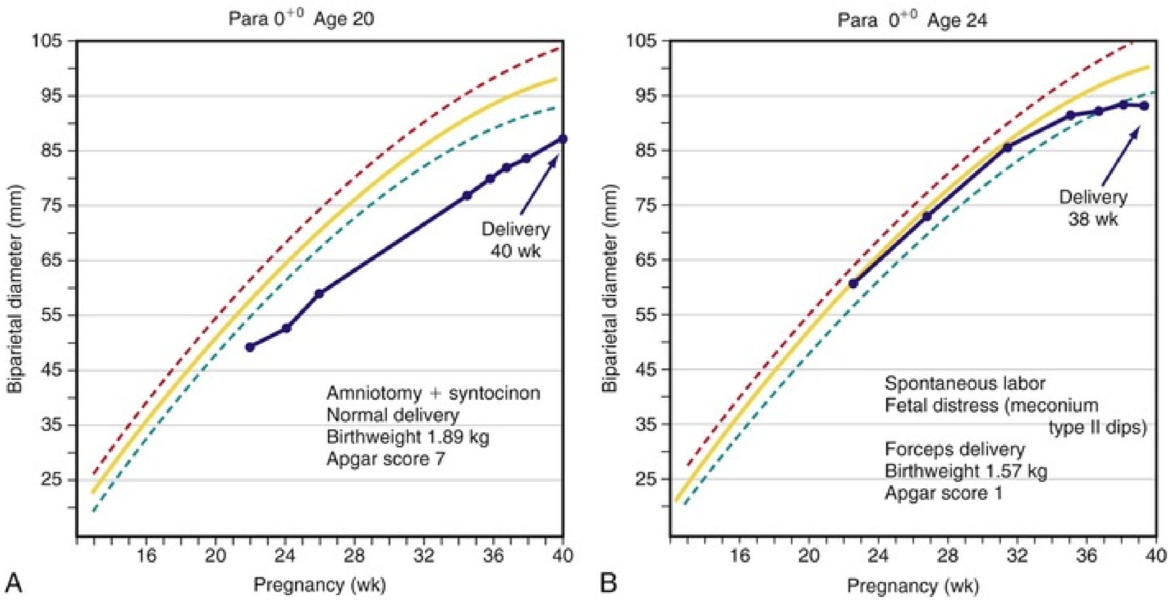

FIG. 115.3 **A,** Example of a “low-profile” growth restriction pattern in an uneventful pregnancy and labor. The baby cried at 1 min, and hypoglycemia did not develop. Birthweight was below the 5th percentile for gestational age. **B,** Example of a “late-flattening” growth restriction pattern. The mother had a typical history of preeclampsia, and the infant had intrapartum fetal distress, a low Apgar score, and postnatal hypoglycemia. Birthweight was below the 5th percentile for gestational age. (From Campbell S: Fetal growth, *Clin Obstet Gynecol* 1:41–65, 1974.)

Fetal maturity and dating are usually assessed by last menstrual period (LMP), assisted reproductive technology (ART)–derived gestational age, or US assessments. Dating by LMP assumes an accurate recall of the 1st day of LMP, a menstrual cycle that lasted 28 days, and ovulation occurring on the 14th day of the cycle, which would place the **estimated delivery date (EDD)** 280 days after LMP. Inaccuracies with any of these parameters can lead to an incorrectly assigned gestational age if the LMP is used for dating. Dating by ART is the most accurate method for assigning gestational age with EDD occurring 266 days after conception (when egg is fertilized by sperm). When US is used for dating, the most accurate assessment of gestational age is by first-trimester ($\leq 13\frac{6}{7}$ wk) US measurement of crown-rump length, which is accurate to within 5-7 days. In contrast, US dating in the second trimester is accurate to 10-14 days, and third trimester is only accurate to 21-30 days. Dating of a pregnancy is critical to determine when delivery should occur, if growth is appropriate during the pregnancy, and when testing and interventions should be offered. The earliest assessment of pregnancy dating should be used throughout the pregnancy unless methodologies used later in pregnancy are significantly different.

115.2

Fetal Distress

Kristen R. Suhrie, Sammy M. Tabbah

Fetal compromise may occur during the antepartum or intrapartum period. It may be asymptomatic in the antenatal period but is often suspected by maternal perception of decreased fetal movement. **Antepartum fetal surveillance** is warranted for women at increased risk for fetal death, including those with a history of stillbirth, intrauterine growth restriction (IUGR), oligohydramnios or polyhydramnios, multiple gestation, rhesus sensitization, hypertensive disorders, diabetes mellitus or other chronic maternal disease, decreased fetal movement, preterm labor, preterm rupture of membranes (PROM), and postterm pregnancy. The predominant cause of antepartum fetal distress is uteroplacental insufficiency, which may manifest clinically as IUGR, fetal hypoxia, increased vascular resistance in fetal blood vessels (Figs. 115.4 and 115.5), and, when severe, mixed respiratory and metabolic (lactic) acidosis. The goal of antepartum fetal surveillance is to identify the fetus at risk of stillbirth such that appropriate interventions (i.e., delivery vs optimization of underlying maternal medical condition) can be implemented to allow for a healthy live-born infant. Table 115.1 lists methods for assessing fetal well-being.

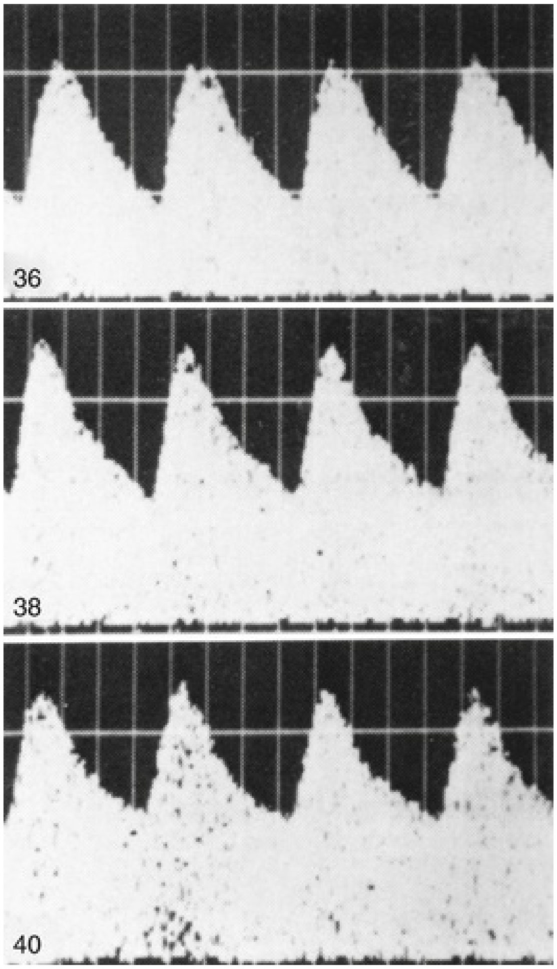

FIG. 115.4 Normal doppler velocity in sequential studies of fetal umbilical artery flow velocity waveforms from one normal pregnancy. Note the systolic peak flow with lower but constant heart flow during diastole. The systolic/diastolic ratio can be determined and, in normal pregnancies, is <3 after the 30th wk of gestation. The *numbers* indicate the weeks of gestation. (From Trudinger B: Doppler US assessment of blood flow. In Creasy RK, Resnik R, editors: *Maternal-fetal medicine: principles and practice,* ed 5, Philadelphia, 2004, Saunders.)

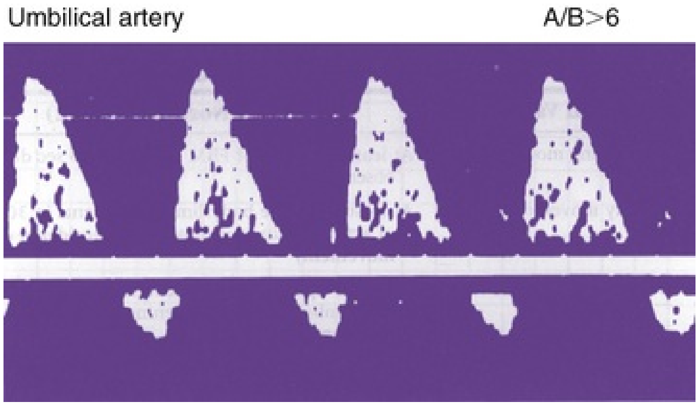

FIG. 115.5 Abnormal umbilical artery Doppler in which the diastolic component shows flow in a reverse direction. This finding occurs in severe intrauterine hypoxia and intrauterine growth restriction. (From Trudinger C: Doppler US assessment of blood flow. In Creasy RK, Resnik R, editors: *Maternal-fetal medicine: principles and practice,* ed 5, Philadelphia, 2004, Saunders.)

Table 115.1

Fetal Diagnosis and Assessment

METHOD	COMMENT(S) AND INDICATION(S)
IMAGING	
Ultrasound (real-time)	Biometry (growth), anomaly detection, number of fetuses, sites of calcification
	Biophysical profile
	Amniotic fluid volume, hydrops
Ultrasound (Doppler)	Velocimetry (blood flow velocity)
	Detection of increased vascular resistance in the umbilical artery secondary to placental insufficiency
	Detection of fetal anemia (MCA Doppler)
MRI	Defining of lesions before fetal surgery
	Better delineation of fetal CNS anatomy
FLUID ANALYSIS	
Amniocentesis	Karyotype or microarray (cytogenetics), biochemical enzyme analysis, molecular genetic DNA diagnosis, or α-fetoprotein determination
	Bacterial culture, pathogen antigen, or genome detection (PCR)
Cordocentesis (percutaneous umbilical blood sampling)	Detection of blood type, anemia, hemoglobinopathies, thrombocytopenia, polycythemia, acidosis, hypoxia, thrombocytopenia, IgM antibody response to infection
	Rapid karyotyping and molecular DNA genetic diagnosis
	Fetal therapy (see Table 115.5)
FETAL TISSUE ANALYSIS	
Chorionic villus biopsy	Cytogenetic and molecular DNA analysis, enzyme assays
Circulating fetal DNA	Noninvasive molecular DNA genetic analysis including microarray analysis and chromosome number (screening method)
MATERNAL SERUM α-FETOPROTEIN CONCENTRATION	
Elevated	Twins, neural tube defects (anencephaly, spina bifida), intestinal atresia, hepatitis,

	nephrosis, fetal demise, incorrect gestational age
Reduced	Trisomies, aneuploidy
MATERNAL CERVIX	
Fetal fibronectin	Indicates possible risk of preterm birth
Transvaginal cervical length	Short length suggests possible risk of preterm birth
Bacterial culture	Identifies risk of neonatal infection (group B streptococcus, *Neisseria gonorrhoeae, Chlamydia trachomatis*)
Amniotic fluid	Determination of premature rupture of membranes (PROM)
ANTEPARTUM BIOPHYSICAL MONITORING	
Nonstress test	Fetal distress; hypoxia
Biophysical profile and modified biophysical profile	Fetal distress; hypoxia
Intrapartum fetal heart rate monitoring	See Fig. 115.6

The most common noninvasive tests are the nonstress test (**NST**) and the biophysical profile (**BPP**). The NST monitors the presence of fetal heart rate (**FHR**) accelerations that follow fetal movement. A reactive (normal) NST result demonstrates 2 FHR accelerations of at least 15 beats/min above the baseline FHR lasting 15 sec during 20 min of monitoring. A nonreactive NST result suggests possible fetal compromise and requires further assessment with a BPP. Although the NST has a low false-negative rate, it does have a high false-positive rate, which is often remedied by the BPP. The full BPP assesses fetal breathing, body movement, tone, NST, and amniotic fluid volume. It effectively combines acute and chronic indicators of fetal well-being, which improves the predictive value of abnormal testing (Table 115.2). A score of 2 or 0 is given for each observation. A total score of 8-10 is reassuring; a score of 6 is equivocal, and retesting should be done in 12-24 hr; and a score of 4 or less warrants immediate evaluation and possible delivery. The BPP has good negative predictive value. The modified BPP consists of the combination of an US estimate of amniotic fluid volume (the amniotic fluid index) and the NST. When results of both are normal, fetal compromise is very unlikely. Signs of progressive compromise seen on Doppler US include reduced, absent, or reversed diastolic waveform velocity in the fetal aorta or umbilical artery (see Fig. 115.5 and Table 115.1). The umbilical vein and ductus venosus waveforms are also used to assess the degree of fetal compromise. Fetuses at highest risk of stillbirth often have combinations of abnormalities, such as growth restriction, oligohydramnios, reversed diastolic Doppler umbilical artery blood flow velocity, and a low BPP.

Table 115.2

Biophysical Profile Scoring: Technique and Interpretation

BIOPHYSICAL VARIABLE	NORMAL SCORE (2)	ABNORMAL SCORE (0)
Fetal breathing movements (FBMs)	At least 1 episode of FBM of at least 30 sec duration in 30 min observation	Absence of FBM or no episode ≥30 sec in 30 min
Gross body movement	At least 3 discrete body/limb movements in 30 min (episodes of active continuous movement considered a single movement)	2 or fewer episodes of body/limb movements in 30 min
Fetal tone	At least 1 episode of active extension with return to flexion of fetal limb(s) or trunk Opening and closing of hand considered evidence of normal tone	Either slow extension with return to partial flexion or movement of limb in full extension or absence of fetal movement with the hand held in complete or partial deflection
Reactive fetal heart rate (FHR)	At least 2 episodes of FHR acceleration of ≥15 beats/min and at least 15 sec in duration associated with fetal movement in 30 min	Less than 2 episodes of acceleration of FHR or acceleration of <15 beats/min in 30 min
Quantitative amniotic fluid (AF) volume[*]	At least 1 pocket of AF that measures at least 2 cm in 2 perpendicular planes	Either no AF pockets or a pocket <2 cm in 2 perpendicular planes

[*] Modification of the criteria for reduced amniotic fluid from <1 cm to <2 cm would seem reasonable. Ultrasound is used for biophysical assessment of the fetus.

From Creasy RK, Resnik R, Iams JD, editors: *Maternal-fetal medicine: principles and practice,* ed 5, Philadelphia, 2004, Saunders.

Fetal compromise *during labor* may be detected by monitoring the FHR, uterine pressure, and fetal scalp blood pH (Fig. 115.6). **Continuous fetal heart rate monitoring** detects abnormal cardiac patterns by instruments that compute the beat-to-beat FHR from a fetal electrocardiographic signal. Signals are derived either from an electrode attached to the fetal presenting part, from an ultrasonic transducer placed on the maternal abdominal wall to detect continuous ultrasonic waves reflected from the contractions of the fetal heart, or from a phonotransducer placed on the mother's abdomen. Uterine contractions are recorded from an intrauterine pressure catheter or from an external tocotransducer applied to the maternal abdominal wall overlying the uterus. FHR patterns show various characteristics, some of which suggest fetal compromise. The baseline FHR is determined over 10 min devoid of accelerations or decelerations. Over the course of pregnancy, the normal baseline FHR gradually decreases from approximately 155 beats/min in early pregnancy to 135 beats/min at term. The normal range throughout pregnancy is 110-160 beats/min. **Tachycardia** (>160 beats/min) is associated with early fetal hypoxia, maternal fever, maternal hyperthyroidism, maternal β-sympathomimetic drug or atropine therapy, fetal anemia, infection, and some fetal arrhythmias. Arrhythmias do not generally occur with congenital heart disease and may resolve spontaneously at birth. **Fetal bradycardia** (<110 beats/min) may be normal (e.g., 105-110 beats/min) but may occur with fetal hypoxia, placental transfer of local anesthetic agents and β-adrenergic blocking agents, and occasionally, heart block with or without congenital heart disease.

FIG. 115.6 **Patterns of periodic fetal heart rate (FHR) deceleration. The tracing in A shows early deceleration occurring during the peak of uterine contractions as a result of pressure on the fetal head. B, Late deceleration caused by uteroplacental insufficiency. C, Variable deceleration as a result of umbilical cord compression. *Arrows* denote the time relationship between the onset of FHR changes and uterine contractions. (From Hon EH: *An atlas of fetal heart rate patterns,* New Haven, CT, 1968, Harty Press.)**

Normally, the baseline FHR is variable as a result of opposing forces from the fetal sympathetic and parasympathetic nervous systems. **Variability** is classified as follows: *absence of variability*, if an amplitude change is undetectable;

minimal variability, if amplitude range is ≤5 beats/min; *moderate* variability, if amplitude range is 6-25 beats/min; and *marked* variability, if amplitude range is >25 beats/min. Variability may be decreased or lost with fetal hypoxemia or the placental transfer of drugs such as atropine, diazepam, promethazine, magnesium sulfate, and most sedative and narcotic agents. Prematurity, the sleep state, and fetal tachycardia may also diminish beat-to-beat variability.

Accelerations or decelerations of the FHR in response to or independent of uterine contractions may also be monitored (see Fig. 115.6). An **acceleration** is an abrupt increase in FHR of ≥15 beats/min in ≥15 sec. The presence of accelerations or moderate variability reliably predicts the absence of fetal metabolic acidemia. However, their absence does not reliably predict fetal acidemia or hypoxemia. **Early decelerations** are a physiologic vagal response to uterine contractions, with resultant fetal head compression, and represent a repetitive pattern of gradual decrease and return of the FHR that is coincidental with the uterine contraction (Table 115.3). **Variable decelerations** are associated with umbilical cord compression and are characterized by a V or U shaped pattern, are abrupt in onset and resolution, and may occur with or without uterine contractions.

Table 115.3

Characteristics of Decelerations of Fetal Heart Rate (FHR)

LATE DECELERATION
Visually apparent, usually symmetric *gradual* decrease and return of the FHR associated with a uterine contraction. A *gradual* FHR decrease is defined as duration of ≥30 sec from the onset to the nadir of the FHR. The decrease in FHR is calculated from the onset to the nadir of the deceleration. The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction. In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively.
EARLY DECELERATION
Visually apparent, usually symmetric *gradual* decrease and return of the FHR associated with a uterine contraction. A *gradual* FHR decrease is defined as duration of ≥30 sec from the onset to the FHR nadir. The decrease in FHR is calculated from the onset to the nadir of the deceleration. The nadir of the deceleration occurs at the same time as the peak of the contraction. In most cases, the onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the contraction, respectively.
VARIABLE DECELERATION
Visually apparent, *abrupt* decrease in FHR. An *abrupt* FHR decrease is defined as duration <30 sec from the onset of the deceleration to the beginning of the FHR nadir of the deceleration. The decrease in FHR is calculated from the onset to the nadir of the deceleration.

The decrease in FHR is ≥15 beats/min, lasting ≥15 sec, and <2 min in duration. When variable decelerations are associated with uterine contractions, their onset, depth, and duration commonly vary with successive uterine contractions.

From Macones GA, Hankins GDV, Spong CY, et al: The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines, *Obstet Gynecol* 112:661–666, 2008.

Late decelerations are associated with fetal hypoxemia and are characterized by onset after a uterine contraction is well established and persists into the interval following resolution of the contraction. The late deceleration pattern is usually associated with maternal hypotension or excessive uterine activity, but it may be a response to any maternal, placental, umbilical cord, or fetal factor that limits effective oxygenation of the fetus. The significance of late decelerations varies according to the underlying clinical context. They are most likely to be associated with true fetal hypoxemia/acidemia when they are recurrent and occur in conjunction with decreased or absent variability. Late decelerations represent a compensatory, chemoreceptor-mediated response to fetal hypoxemia. The transient decrease in FHR serves to increase ventricular preload during the peak of hypoxemia (i.e., at the crest of a uterine contraction). If fetal acidemia progresses, late decelerations may become less pronounced or absent, indicating severe hypoxic depression of myocardial function. Prompt delivery is indicated if late decelerations are unresponsive to oxygen supplementation, hydration, discontinuation of labor stimulation, and position changes. Approximately 10–15% of term fetuses have *terminal* (just before delivery) FHR decelerations that are usually benign if they last <10 min before delivery.

A 3-tier system has been developed by a panel of experts for interpretation of FHR tracings (Table 115.4). **Category I tracings** are normal and are strongly predictive of normal fetal acid-base status at the time of the observation. **Category II tracings** are not predictive of abnormal fetal status, but there is insufficient evidence to categorize them as category I or III; therefore further evaluation, surveillance, and reevaluation are indicated. **Category III tracings** are abnormal and predictive of abnormal fetal acid-base status at the time of observation. Category III tracings require prompt evaluation and efforts to resolve expeditiously the abnormal FHR as previously discussed for late decelerations.

Table 115.4

Three-Tier Fetal Heart Rate (FHR) Interpretation System

CATEGORY I
Category I FHR tracings include all the following: • Baseline rate: 110-160 beats/min • Baseline FHR variability: moderate • Late or variable decelerations: absent • Early decelerations: present or absent • Accelerations: present or absent
CATEGORY II
Category II FHR tracings include all FHR tracings not categorized as category I or category III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples of category II FHR tracings include any of the following:
Baseline Rate
• Bradycardia not accompanied by absence of baseline variability • Tachycardia
Baseline FHR Variability
• Minimal baseline variability • Absence of baseline variability not accompanied by recurrent decelerations • Marked baseline variability
Accelerations
• Absence of induced accelerations after fetal stimulation
Periodic or Episodic Decelerations
• Recurrent variable decelerations accompanied by minimal or moderate baseline variability • Prolonged deceleration, ≥2 min but <10 min • Recurrent late decelerations with moderate baseline variability • Variable decelerations with other characteristics, such as slow return to baseline, “overshoots,” and “shoulders”
CATEGORY III
Category III FHR tracings include either: • Absence of baseline FHR variability *or* Any of the following: • Recurrent late decelerations • Recurrent variable decelerations • Bradycardia • Sinusoidal pattern

Adapted from Macones GA, Hankins GDV, Spong CY, et al: The 2008 National Institute of Child Health and Human Development workshop report on electronic fetal monitoring: update on definitions, interpretation, and research guidelines, *Obstet Gynecol* 112:661–666, 2008.

Umbilical cord blood samples obtained at delivery are useful to document fetal acid-base status. Although the exact cord blood pH value that defines significant fetal acidemia is unknown, an umbilical artery pH <7.0 has been associated with greater need for resuscitation and a higher incidence of respiratory, gastrointestinal, cardiovascular, and neurologic complications. Nonetheless, in many cases, even when a low pH is detected, newborn infants are neurologically normal.

115.3

Maternal Disease and the Fetus

Kristen R. Suhrie, Sammy M. Tabbah

Infectious Diseases

See Table 114.3 in Chapter 114 for a list of common maternal infectious diseases that impact the fetus and newborn.

Almost any maternal infection with severe systemic manifestations may result in miscarriage, stillbirth, or premature labor. Whether these results are a consequence of infection of the fetus or are secondary to maternal illness is not always clear. Another important factor to consider when dealing with infectious diseases in pregnancy is the timing of infection. In general, infections that occur earlier in the pregnancy (first or second trimester) are more likely to result in miscarriage or problems with organogenesis, such as the neuromigrational abnormalities seen in newborns with congenital CMV infections.

Cytomegalovirus (CMV) is the most common congenital infection, affecting 0.2–2.2% of all neonates (see Chapter 282). Perinatal transmission can occur at any time during the pregnancy; however, the most devastating sequelae occur with first-trimester infection. After a primary infection, 12–18% of neonates will have signs and symptoms at birth, and as many as 25% can develop long-term complications. The most common complication is **congenital hearing loss** . Severely affected infants have an associated 30% mortality, and 65–80% of survivors develop severe neurologic morbidity. A mother with a history of CMV may experience reactivation of the disease or may be infected with a different strain of the virus and transmit the infection to the fetus. Currently, there are no well-studied or validated antenatal therapies targeted toward decreasing disease severity or preventing congenital infection in the setting of primary maternal CMV infection. Preliminary data from some studies have demonstrated promise with drugs such as valganciclovir and CMV-specific hyperimmune globulin, but confirmatory data are lacking. For this reason, the American College of Obstetricians and Gynecologists (ACOG) does not recommend antenatal therapy for congenital CMV infection outside of an established research protocol.

Noninfectious Diseases (see Table 114.2)

Maternal diabetes increases the risk for neonatal hypoglycemia, hypocalcemia, respiratory distress syndrome and other respiratory problems, feeding difficulties, polycythemia, macrosomia, growth restriction, myocardial dysfunction, jaundice, and congenital malformations (see Chapter 127.1). There is an increased risk of uteroplacental insufficiency, polyhydramnios, and fetal demise in poorly controlled diabetic mothers. **Preeclampsia-eclampsia** , **chronic hypertension** , and **chronic renal disease** can result in IUGR, prematurity, and fetal death, all probably caused by diminished uteroplacental perfusion.

Uncontrolled maternal **hypothyroidism** or **hyperthyroidism** is responsible for relative infertility, spontaneous abortion, premature labor, and fetal death. Hypothyroidism in pregnant women (even if mild or asymptomatic) can adversely affect neurodevelopment of the child, especially if the newborn is found to have congenital hypothyroidism.

Maternal **immunologic diseases** such as idiopathic thrombocytopenic purpura, systemic lupus erythematosus, myasthenia gravis, and Graves disease, all of which are mediated by immunoglobulin G autoantibodies that can cross the placenta, frequently cause transient illness in the newborn. Maternal autoantibodies to the folate receptor are associated with neural tube defects (**NTDs**), whereas maternal immunologic sensitization to fetal antigens may be associated with neonatal alloimmune hepatitis and neonatal alloimmune thrombocytopenia (**NAIT**).

Untreated metabolic disorders such as maternal **phenylketonuria** (PKU) results in miscarriage, congenital cardiac malformations, and injury to the brain of a nonphenylketonuric heterozygous fetus. Women whose PKU is well controlled before conception can avoid these complications and have a normal newborn.

115.4

Medication and Teratogen Exposure

Kristen R. Suhrie, Sammy M. Tabbah

When an infant or child has a congenital malformation or is developmentally delayed, the parents often wrongly blame themselves and attribute the child's problems to events that occurred during pregnancy. Because benign infections occur, and several nonteratogenic drugs are often taken during many pregnancies, the pediatrician must evaluate the presumed viral infections and the drugs ingested to help parents understand their child's birth defect. The causes of approximately 40% of congenital malformations are unknown. Although only relatively few agents are recognized to be teratogenic in humans, new agents continue to be identified. An excellent internet-based resource known as **Reprotox** (reprotox.org) provides comprehensive and routinely updated summaries on drugs and other potentially teratogenic agents in pregnancy. Overall, only 10% of anomalies are caused by recognizable teratogens (see Chapter 128). The time of exposure that is most likely to cause injury is usually during organogenesis at <60 days of gestation. Specific agents produce predictable lesions. Some agents have a dose or *threshold* effect, below which no alterations in growth, function, or structure occur. Genetic variables such as the presence of specific enzymes may metabolize a benign agent into a more toxic, teratogenic form (e.g., phenytoin conversion to its epoxide). In many circumstances the same agent and dose may not consistently produce the lesion.

Reduced enzyme activity of the folate methylation pathway, particularly the formation of 5-methyltetrahydrofolate, may be responsible for NTDs or other birth defects. The common thermolabile mutation of 5,10-methylene tetrahydrofolate reductase may be one of the enzymes responsible. Folate supplementation for all pregnant women (by direct fortification of cereal grains, which is mandatory in the United States), and oral folic acid tablets taken during organogenesis may overcome this genetic enzyme defect, thus reducing the incidence of NTDs and perhaps other birth defects.

The U.S. Food and Drug Administration (FDA) classifies drugs into 5 pregnancy risk categories. **Category A** drugs pose no risk on the basis of evidence from controlled human studies. For **category B** drugs, either no risk has been shown in animal studies but no adequate studies have been done in humans, *or* some risk has been shown in animal studies but these results are not confirmed by human studies. For **category C** drugs, either definite risk has been shown in animal studies but no adequate human studies have been performed, *or* no data are available from either animal or human studies. **Category D** includes drugs with some risk but with a benefit that may exceed that risk for the treated life-threatening condition, such as streptomycin for tuberculosis. **Category X** is for drugs that are contraindicated in pregnancy on the basis of animal and human evidence and for which the risk exceeds the benefits.

The use of medications or herbal remedies during pregnancy is potentially harmful to the fetus. Consumption of medications occurs during the majority of pregnancies. The average mother has taken 4 drugs other than vitamins or iron during pregnancy. Almost 40% of pregnant women receive a drug for which human safety during pregnancy has not been established (category C pregnancy risk). Moreover, many women are exposed to potential reproductive toxins, such as occupational, environmental, or household chemicals, including solvents, pesticides, and hair products. The effects of drugs taken by the mother vary considerably, especially in relation to the time in pregnancy when they are taken and the fetal genotype for drug-metabolizing enzymes.

Miscarriage or **congenital malformations** result from the maternal ingestion of teratogenic drugs during the period of organogenesis. Maternal medications taken later, particularly during the last few weeks of gestation or during labor, tend to affect the function of specific organs or enzyme systems, and these adversely affect the neonate rather than the fetus (Tables 115.5 and 115.6). The effects of drugs may be evident immediately in the delivery room or later in the neonatal period, or they may be delayed even longer. The administration of diethylstilbestrol during pregnancy, for instance, increased the risk for vaginal adenocarcinoma in female offspring in the 2nd or 3rd decade of life.

Table 115.5

Agents Acting on Pregnant Women That May Adversely Affect the Structure or Function of the Fetus and Newborn

DRUG	EFFECT ON FETUS
Accutane (isotretinoin)	Facial-ear anomalies, heart disease, CNS anomalies
Alcohol	Congenital cardiac, CNS, limb anomalies; IUGR; developmental delay; attention deficits; autism
Aminopterin	Abortion, malformations
Amphetamines	Congenital heart disease, IUGR, withdrawal
ACE inhibitors, angiotensin receptor antagonists	Oligohydramnios, IUGR, renal failure, Potter-like syndrome
Azathioprine	Abortion
Busulfan (Myleran)	Stunted growth; corneal opacities; cleft palate; hypoplasia of ovaries, thyroid, and parathyroids
Carbamazepine	Spina bifida, possible neurodevelopmental delay
Carbimazole	Scalp defects, choanal atresia, esophageal atresia, developmental delay
Carbon monoxide	Cerebral atrophy, microcephaly, seizures
Chloroquine	Deafness
Chorionic villus sampling	Probably no effect, possibly limb reduction

Cigarette smoking	LBW for gestational age
Cocaine/crack	Microcephaly, LBW, IUGR, behavioral disturbances
Cyclophosphamide	Multiple malformations
Danazol	Virilization
17α-Ethinyl testosterone (Progestoral)	Masculinization of female fetus
Hyperthermia	Spina bifida
Infliximab	Possible increased risk of live vaccine associated disease in infant; neutropenia
Lithium	Ebstein anomaly, macrosomia
Lopinavir-ritonavir	Transient adrenal dysfunction
6-Mercaptopurine	Abortion
Methyl mercury	Minamata disease, microcephaly, deafness, blindness, mental retardation
Methyltestosterone	Masculinization of female fetus
Misoprostol	Arthrogryposis, cranial neuropathies (Möbius syndrome), equinovarus
Mycophenolate mofetil	Craniofacial, limb, cardiovascular, CNS anomalies
Norethindrone	Masculinization of female fetus
Penicillamine	Cutis laxa syndrome
Phenytoin	Congenital anomalies, IUGR, neuroblastoma, bleeding (vitamin K deficiency)
Polychlorinated biphenyls	Skin discoloration—thickening, desquamation, LBW, acne, developmental delay
Prednisone	Oral clefts
Progesterone	Masculinization of female fetus
Quinine	Abortion, thrombocytopenia, deafness
Selective serotonin reuptake inhibitors	Small increased risk of congenital anomalies, persistent pulmonary hypertension of newborn
Statins	IUGR, limb deficiencies, VACTERAL
Stilbestrol (diethylstilbestrol [DES])	Vaginal adenocarcinoma in adolescence
Streptomycin	Deafness
Tetracycline	Retarded skeletal growth, pigmentation of teeth, hypoplasia of enamel, cataract, limb malformations
Thalidomide	Phocomelia, deafness, other malformations
Toluene (solvent abuse)	Craniofacial abnormalities, prematurity, withdrawal symptoms, hypertonia
Topiramate	Cleft lip
Trimethadione and paramethadione	Abortion, multiple malformations, mental retardation
Valproate	CNS (spina bifida), facial and cardiac anomalies, limb defects, impaired neurologic function, autism spectrum disorder
Vitamin D	Supravalvular aortic stenosis, hypercalcemia
Warfarin (Coumadin)	Fetal bleeding and death, hypoplastic nasal structures

ACE, Angiotensin-converting enzyme; CNS, central nervous system; IUGR, intrauterine growth restriction; LBW, low birthweight; VACTERAL, vertebral, anal, cardiac, tracheoesophageal fistula, renal, arterial, limb.

Table 115.6

Agents Acting on Pregnant Women That May Adversely Affect the Newborn Infant*

Acebutolol—IUGR, hypotension, bradycardia

Acetazolamide—metabolic acidosis
Amiodarone—bradycardia, hypothyroidism
Anesthetic agents (volatile)—CNS depression
Adrenal corticosteroids—adrenocortical failure (rare)
Ammonium chloride—acidosis (clinically inapparent)
Aspirin—neonatal bleeding, prolonged gestation
Atenolol—IUGR, hypoglycemia
Baclofen—withdrawal
Blue cohosh herbal tea—neonatal heart failure
Bromides—rash, CNS depression, IUGR
Captopril, enalapril—transient anuric renal failure, oligohydramnios
Caudal-paracervical anesthesia with mepivacaine (accidental introduction of anesthetic into scalp of baby)—bradypnea, apnea, bradycardia, convulsions
Cholinergic agents (edrophonium, pyridostigmine)—transient muscle weakness
CNS depressants (narcotics, barbiturates, benzodiazepines) during labor—CNS depression, hypotonia
Cephalothin—positive direct Coombs test reaction
Dexamethasone—periventricular leukomalacia
Fluoxetine and other SSRIs—transient neonatal withdrawal, hypertonicity, minor anomalies, preterm birth, prolonged QT interval
Haloperidol—withdrawal
Hexamethonium bromide—paralytic ileus
Ibuprofen—oligohydramnios, pulmonary hypertension
Imipramine—withdrawal
Indomethacin—oliguria, oligohydramnios, intestinal perforation, pulmonary hypertension
Intravenous fluids during labor (e.g., salt-free solutions)—electrolyte disturbances, hyponatremia, hypoglycemia
Iodide (radioactive)—goiter
Iodides—goiter
Lead—reduced intellectual function
Magnesium sulfate—respiratory depression, meconium plug, hypotonia
Methimazole—goiter, hypothyroidism
Morphine and its derivatives (addiction)—withdrawal symptoms (poor feeding, vomiting, diarrhea, restlessness, yawning and stretching, dyspnea and cyanosis, fever and sweating, pallor, tremors, convulsions)
Naphthalene—hemolytic anemia (in G6PD-deficient infants)
Nitrofurantoin—hemolytic anemia (in G6PD-deficient infants)
Oxytocin—hyperbilirubinemia, hyponatremia
Phenobarbital—bleeding diathesis (vitamin K deficiency), possible long-term reduction in IQ, sedation
Primaquine—hemolytic anemia (in G6PD-deficient infants)
Propranolol—hypoglycemia, bradycardia, apnea
Propylthiouracil—goiter, hypothyroidism
Pyridoxine—seizures
Reserpine—drowsiness, nasal congestion, poor temperature stability
Sulfonamides—interfere with protein binding of bilirubin; kernicterus at low levels of serum bilirubin, hemolysis with G6PD deficiency
Sulfonylurea agents—refractory hypoglycemia
Sympathomimetic (tocolytic β-agonist) agents—tachycardia
Thiazides—neonatal thrombocytopenia (rare)
Tumor necrosis factor blocking agents—neutropenia, possible increased risk of infection during 1st yr of life
Valproate—developmental delay
Zolpidem (Ambien)—low birthweight

[*] See also Table 115.5 .

CNS, Central nervous system; G6PD, glucose-6-phosphate dehydrogenase; IUGR, intrauterine growth restriction; SSRI, selective serotonin reuptake inhibitor.

Often the risk of controlling maternal disease must be balanced with the risk of possible complications in the fetus. Most women with epilepsy have normal fetuses. Nonetheless, several commonly used **antiepileptic drugs** are associated with congenital malformations. Infants exposed to valproic acid may have multiple anomalies, including NTDs, hypospadias, facial anomalies, cardiac anomalies, and limb defects. In addition, they have lower developmental index scores than unexposed infants and infants exposed to other common antiepileptic drugs.

Moderate or high alcohol intake (≥7 drinks/wk or ≥3 drinks on multiple occasions) is a risk for **fetal alcohol syndrome** . The exposed fetuses are at risk for growth failure, central nervous system abnormalities, cognitive defects, and behavioral problems. It must be emphasized, however, that there is no known dose-response threshold for fetal alcohol exposure; therefore pregnant women should be counseled toward complete abstinence. **Smoking** during pregnancy is associated with IUGR and facial clefts.

Chronic **heroin (opioid)** use throughout pregnancy is associated with an increased risk of fetal growth restriction, placental abruption, stillbirth, preterm birth, and intrauterine passage of meconium. Opiates readily cross the placenta; therefore these effects are postulated to be related to cyclic fetal opiate withdrawal. Furthermore, the lifestyle issues surrounding opioid abuse, including lack of or late entry into prenatal care, place the mother at higher risk of adverse pregnancy outcome. Therefore, opioid maintenance therapy with either methadone or buprenorphine is recommended for opioid-dependent pregnant women to prevent complications of illicit opioid use and narcotic withdrawal, encourage prenatal care and drug treatment, reduce criminal activity, and avoid risks to the patient of associating with a drug culture.

Neonatal abstinence syndrome (NAS) occurs in the setting of opioid maintenance treatment or illicit drug use; thus opiate maintenance therapy is not preventive in this regard. **Methadone** is considered first-line therapy for treatment of opioid dependence in pregnancy; **buprenorphine** is an acceptable alternative in the appropriately selected patient. There is no established, dose-response relationship between methadone or buprenorphine and risk/severity of NAS, so the lowest effective dose to eliminate maternal cravings/withdrawal is recommended. Methadone is associated with a lower birthweight than buprenorphine. Both medications have a similar rate of NAS requiring treatment (approximately 50%); however, the use of antenatal buprenorphine has been associated with significantly lower dosages of morphine to treat NAS and significantly shorter NAS-related hospital stays than methadone. For these reasons, buprenorphine may be preferred under certain circumstances.

The specific mechanism of action is known or postulated for very few teratogens. **Warfarin** , a vitamin K antagonist used for anticoagulation, prevents the carboxylation of γ-carboxyglutamic acid, which is a component of osteocalcin and other vitamin K–dependent bone proteins. The teratogenic effect of warfarin on developing cartilage, especially nasal cartilage, appears to be avoided if the pregnant woman's anticoagulation treatment is switched from warfarin to heparin for the period between weeks 6 and 12 of gestation. However, the risk of intracranial hemorrhage is maintained with exposure throughout pregnancy. For these reasons, **low-molecular-weight heparin** is the preferred anticoagulant when treating pregnant women.

Hypothyroidism in the fetus may be caused by maternal ingestion of an excessive amount of iodide or propylthiouracil; each interferes with the conversion of inorganic to organic iodides. Furthermore, there is an interaction between genetic factors and susceptibility to certain drugs or environmental toxins. Phenytoin teratogenesis, for example, may be mediated by genetic differences in the enzymatic production of epoxide metabolites. Polymorphisms of genes encoding enzymes that metabolize the polycyclic aromatic hydrocarbons in cigarette smoke influence the growth-restricting effects of smoking on the fetus.

Recognition of teratogenic potential from a variety of sources offers the opportunity to prevent related birth defects. If a pregnant woman is informed of the potentially harmful effects of alcohol, tobacco, and illicit drugs on her unborn infant, she may be motivated to avoid consumption of these substances during pregnancy. A woman with insulin-dependent diabetes mellitus may significantly decrease her risk for having a child with birth defects by achieving good control of her disease before conception. Lastly, in view of the limits of current knowledge regarding the fetal effects of maternal medication use, drugs and herbal agents should only be prescribed during pregnancy after carefully weighing the maternal benefit against the risk of fetal harm.

115.5

Radiation

Kristen R. Suhrie, Sammy M. Tabbah

See also Chapter 736 .

Accidental exposure of a pregnant woman to radiation is a common cause for anxiety about whether her fetus will have genetic abnormalities or birth defects. It is unlikely that exposure to diagnostic radiation will cause gene mutations; no increase in genetic abnormalities has been identified in the offspring exposed as unborn fetuses to the atomic bomb explosions in Japan in 1945.

A more realistic concern is whether the exposed human fetus will show birth defects or a higher incidence of malignancy. The background fetal radiation exposure in a given pregnancy is approximately 0.1 rad. The estimated radiation dose for most radiographs is <0.1 rad and for most CT scans <5 rad (maximum recommended radiation exposure in pregnancy). Imaging studies with high radiation exposure (e.g., CT scans) can be modified to ensure that radiation doses are kept as low as possible. Thus, single diagnostic studies do not result in radiation doses high enough to affect the embryo or fetus. Pregnancy termination should not be recommended only on the basis of diagnostic radiation exposure. Most of the evidence suggests that usual fetal radiation exposure does not increase the risk of childhood leukemia and other cancers; although some sources suggest that a 1-2 rad fetal radiation exposure may confer a 1.5-2–fold increased risk of childhood leukemia, which has a background risk of 1 in 3,000. Before implantation (0-2 wk postconception), radiation doses of 5-10 rad may result in miscarriage. At 2-8 wk gestation, doses in excess of 20 rad have been associated with congenital anomalies and fetal growth restriction. Severe intellectual disabilities can occur with exposures of ≥25 rad before 25 wk gestation. The available data suggest no harmful fetal effect of diagnostic MRI or US, which do not involve radiation.

115.6

Intrauterine Diagnosis of Fetal Disease

Kristen R. Suhrie, Sammy M. Tabbah

See Table 115.1 and Chapter 115.2 .

Diagnostic procedures are used to identify fetal diseases when direct fetal treatment is possible, to better direct neonatal care, when a decision is made to deliver a viable but premature infant to avoid intrauterine fetal demise, or when pregnancy termination is being considered. Fetal assessment is also indicated in a broader context when the family, medical, or reproductive history of the mother suggests the presence of a high-risk pregnancy or a high-risk fetus (see Chapters 114 and 115.3).

Various methods are used for identifying fetal disease (see Table 115.1). Fetal US imaging may detect fetal growth abnormalities (by previously outlined biometric measurements) or fetal malformations (Fig. 115.7). Serial determinations of growth velocity and the head-to-abdomen circumference ratio enhance the ability to detect IUGR. Real-time US may identify placental abnormalities (abruptio placentae, placenta previa) and fetal anomalies such as hydrocephalus, NTDs, duodenal atresia, diaphragmatic hernia, renal agenesis, bladder outlet obstruction, congenital heart disease, limb abnormalities, sacrococcygeal teratoma, cystic hygroma, omphalocele, gastroschisis, and hydrops (Table 115.7).

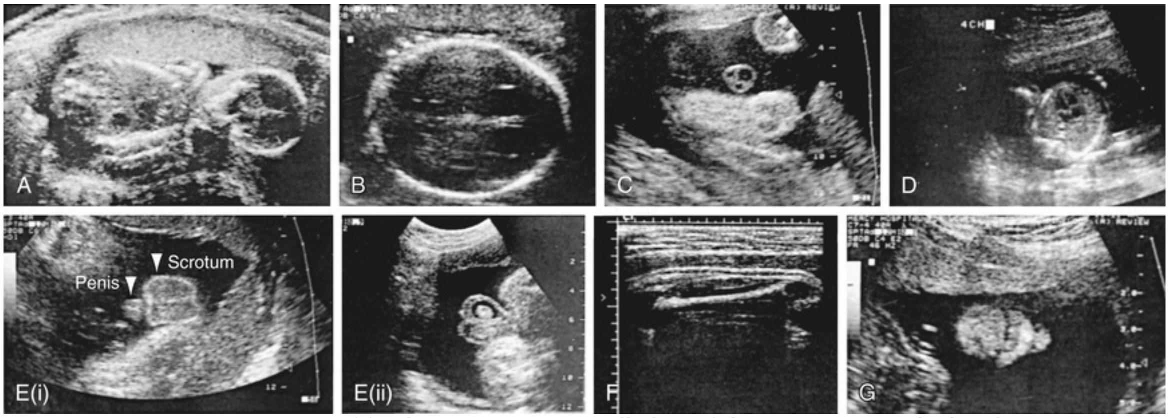

FIG. 115.7 **Assessment of fetal anatomy. A, Overall view of the uterus at 24 wk showing a longitudinal section of the fetus and an anterior placenta. B, Transverse section at the level of the lateral ventricle at 18 wk showing (*on the right*) prominent anterior horns of the lateral ventricles on either side of the midline echo of the falx. C, Cross section of the umbilical cord showing that the lumen of the umbilical vein is much wider than that of the 2 umbilical arteries. D, Four-chambered view of the heart at 18 wk with equal-sized atria. E(i), Normal male genitals near term. E(ii), Hydrocele outlining a testicle within the scrotum projecting into a normal-size pocket of amniotic fluid at 38 wk. Approximately 2% of male infants after birth have clinical evidence of a hydrocele that is often bilateral, not to be confused with subcutaneous edema occurring during vaginal breech birth. F, Section of a thigh near term showing thick subcutaneous tissue (4.6 mm between *markers*) above the femur of a fetus with macrosomia. G, Fetal face viewed from below, showing (*from right to left*) the nose, alveolar margin, and chin at 20 wk. (From Special investigative procedures. In Beischer NA, Mackay EV, Colditz PB, editors: *Obstetrics and the newborn,* ed 3, Philadelphia, 1997, Saunders.)**

Table 115.7

Significance of Fetal Ultrasonographic Anatomic Findings

PRENATAL OBSERVATION	DEFINITION	DIFFERENTIAL DIAGNOSIS	SIGNIFICANCE	POSTNATAL EVALUATION
Dilated cerebral ventricles	Ventriculomegaly ≥10 mm	Hydrocephalus Hydranencephaly Dandy-Walker cyst Agenesis of corpus callosum Volume loss	Transient isolated ventriculomegaly is common and usually benign. Persistent or progressive ventriculomegaly is more worrisome. Identify associated cranial and extracranial anomalies.	Serial head US or MRI Evaluate for extracranial anomalies.
Choroid plexus cysts	Size ~10 mm: unilateral or bilateral 1–3% incidence	Abnormal karyotype (trisomy 18, 21) Increased risk if AMA	Often isolated, benign; resolves by 24-28 wk. Fetus should be examined for other organ anomalies; if	Head US Examine for extracranial anomalies; karyotype if indicated.

			additional anomalies present, amniocentesis should be performed for karyotype.	
Nuchal fold thickening	≥6 mm at 15-20 wk	Cystic hygroma trisomy 21, 18 Turner syndrome (XO) Other genetic syndromes Normal (~25%)	~50% of affected fetuses have chromosome abnormalities. Amniocentesis for karyotype needed.	Evaluate for multiple organ malformations; karyotype if indicated.
Dilated renal pelvis	Pyelectasis ≥4 to 10 mm 0.6–1% incidence	Normal variant Uteropelvic junction obstruction Vesicoureteral reflux Posterior ureteral valves Entopic ureterocele Large-volume nonobstruction	Often “physiologic” and transient Reflux is common. If dilation is >10 mm or associated with caliectasis, pathologic cause should be considered. If large bladder present, posterior urethral valves and megacystis–microcolon hypoperistalsis syndrome should be considered.	Repeat ultrasonography on day 5 and at 1 mo; voiding cystourethrogram, prophylactic antibiotics
Echogenic bowel	0.6% incidence	CF, meconium peritonitis, trisomy 21 or 18, other chromosomal abnormalities cytomegalovirus, toxoplasmosis, GI obstruction, intrauterine bleeding (fetal swallowing of blood)	Often normal Consider CF, aneuploidy, and TORCH.	Sweat chloride and DNA testing Karyotype Surgery for obstruction Evaluation for TORCH
Stomach appearance	Small or absent or with double bubble	Upper GI obstruction (esophageal atresia) Double bubble signifies duodenal atresia Aneuploidy Polyhydramnios Stomach in chest signifies diaphragmatic hernia	Must also consider neurologic disorders that reduce swallowing. >30% with double bubble have trisomy 21.	Chromosomes; kidney, ureter, and bladder radiograph if indicated; upper GI series; neurologic evaluation

CF, Cystic fibrosis; CMV, cytomegalovirus; GI, gastrointestinal; TORCH, toxoplasmosis, other agents, rubella, CMV, herpes simplex syndrome; US, ultrasound.

Real-time US also facilitates performance of needle-guided procedures (i.e. cordocentesis) and the BPP by imaging fetal breathing, body movements, tone, and amniotic fluid volume (see Table 115.2). Doppler velocimetry assesses fetal arterial blood flow (vascular resistance) (see Figs. 115.4 and 115.5). Fetal MRI is used to better define abnormalities detected on US and to help with prognostication (see Fig. 115.1).

Amniocentesis , the transabdominal withdrawal of amniotic fluid during pregnancy for diagnostic purposes (see Table 115.1), is a common obstetric procedure. It is frequently performed to evaluate for infection. It is also done for genetic indications, usually between the 15th and 20th wk of gestation, with results available as soon as 24-48 hr for fluorescence in situ hybridization (FISH) testing and 2-3 wk for microarray testing. The most common indication for genetic amniocentesis is **advanced maternal age** ; the risk for chromosome abnormality at term at age 21 yr is 1 : 525, vs 1 : 6 at age 49 yr. ACOG recommends that all pregnant women be offered amniocentesis to evaluate further for an underlying genetic condition such as Down syndrome. Analysis of amniotic fluid may also help in identifying NTDs (elevation of α-fetoprotein [AFP] and presence of acetylcholinesterase). Additionally, families with a known genetic syndrome may be offered prenatal genetic testing from amniotic fluid or amniocytes obtained via amniocentesis or CVS.

Chorionic villus sampling (CVS) is performed in the first trimester, either transvaginally or transabdominally. The sample obtained is placental in origin, which can sometimes be problematic because aneuploidy may be present in the placenta and not the fetus, a condition known as **confined placental mosaicism** , which can give a false-positive rate as high as 3%. Furthermore, CVS may be associated with a slightly higher risk of fetal loss than amniocentesis.

Amniocentesis can be carried out with little discomfort to the mother. Procedure-related complications are relatively rare, and many can be avoided by using a US-guided approach. These risks include direct damage to the fetus, placental puncture and bleeding with secondary damage to the fetus, stimulation of uterine contraction and premature labor, chorioamnionitis, maternal sensitization to fetal blood, and pregnancy loss. Best available data indicate that the pregnancy loss rate associated with amniocentesis is 1 : 500-900 procedures. Amniocentesis is not recommended before 14 wk of gestation because this has been associated with a higher risk of pregnancy loss, ruptured membranes, and clubfoot.

Cordocentesis , or percutaneous umbilical blood sampling (PUBS), is used to diagnose fetal hematologic abnormalities, genetic disorders, infections, and fetal acidosis (see Table 115.1). Under direct US visualization, a long needle is passed into the umbilical vein at its entrance to the placenta or in a free loop of cord. Transfusion or administration of drugs can be performed through the umbilical vein (Table 115.8). The predominant indication for this procedure is for confirmation of fetal anemia (in Rh isoimmunization) or thrombocytopenia (NAIT), with subsequent transfusion of packed red blood cells or platelets into the umbilical venous circulation.

Table 115.8

Fetal Therapy

DISORDER	POSSIBLE TREATMENT
HEMATOLOGIC	
Anemia with hydrops (erythroblastosis fetalis)	Cordocentesis of umbilical vein with packed red blood cell transfusion
Isoimmune thrombocytopenia	Umbilical vein platelet transfusion, maternal IVIG
Autoimmune thrombocytopenia (ITP)	Maternal steroids and IVIG
METABOLIC/ENDOCRINE	
Maternal phenylketonuria (PKU)	Phenylalanine restriction
Fetal galactosemia	Galactose-free diet (?)
Multiple carboxylase deficiency	Biotin if responsive
Methylmalonic acidemia	Vitamin B_{12} if responsive
21-Hydroxylase deficiency	Dexamethasone if female fetus
Maternal diabetes mellitus	Tight insulin control during pregnancy, labor, and delivery
Fetal goiter	Maternal hyperthyroidism—maternal propylthiouracil
	Fetal hypothyroidism—intraamniotic thyroxine
Bartter syndrome	Maternal indomethacin may prevent nephrocalcinosis and postnatal sodium losses
FETAL DISTRESS	
Hypoxia	Maternal oxygen, position changes
Intrauterine growth restriction	Improve macronutrients and micronutrients if deficient, smoking cessation, treatment of maternal disease, antenatal fetal surveillance
Oligohydramnios, premature rupture of membranes with variable deceleration	Antenatal fetal surveillance
	Approach dependent on etiology
	Amnioinfusion (intrapartum)
Polyhydramnios	Antenatal fetal surveillance
	Approach dependent on etiology
	Amnioreduction if indicated,
Supraventricular tachycardia	Maternal digoxin,[*] flecainide, procainamide, amiodarone, quinidine
Lupus anticoagulant	Maternal aspirin and heparin
Meconium-stained fluid	Amnioinfusion
Congenital heart block	Dexamethasone, pacemaker (with hydrops)
Premature labor	Magnesium sulfate, nifedipine, indomethacin with antenatal corticosteroids (betamethasone)
RESPIRATORY	
Pulmonary immaturity	Betamethasone
Bilateral chylothorax—pleural effusions	Thoracentesis, pleuroamniotic shunt
CONGENITAL ABNORMALITIES [†]	
Neural tube defects	Folate, vitamins (prevention); fetal surgery [‡]

Posterior urethral valves, urethral atresia (lower urinary tract obstruction)	Percutaneous vesicoamniotic shunt
Cystic adenomatoid malformation (with hydrops)	Pleuroamniotic shunt or resection [‡]
Fetal neck masses	Secure an airway with EXIT procedure [‡]
INFECTIOUS DISEASE	
Group B streptococcus colonization	Ampicillin, penicillin
Chorioamnionitis	Antibiotics and delivery
Toxoplasmosis	Spiramycin, pyrimethamine, sulfadiazine, folic acid
Syphilis	Penicillin
Tuberculosis	Antituberculosis drugs
Lyme disease	Penicillin, ceftriaxone
Parvovirus	Intrauterine red blood cell transfusion for hydrops, severe anemia
Chlamydia trachomatis	Azithromycin
HIV-AIDS	Maternal and neonatal antiretroviral therapy (see Chapter 302)
Cytomegalovirus	No approved prenatal treatments
OTHER	
Nonimmune hydrops (anemia)	Umbilical vein packed red blood cell transfusion
Narcotic abstinence (withdrawal)	Maternal methadone maintenance
Sacrococcygeal teratoma (with hydrops)	In utero resection or catheter-directed vessel obliteration
Cardiac rhabdomyoma	Maternal sirolimus
Intrapericardial teratoma	Fetal surgery
CRISPR-Cas9 gene editing	Proof of concept in previable in vitro fertilized human embryos
Twin-twin transfusion syndrome	Repeated amniocentesis, yttrium-aluminum-garnet (YAG) laser photocoagulation of shared vessels
Twin reversed arterial perfusion (TRAP) syndrome	Cord occlusion, radiofrequency ablation
Multifetal gestation	Selective reduction
Neonatal hemochromatosis	Maternal IVIG
Aortic stenosis	In utero valvuloplasty

[*] Drug of choice (may require percutaneous umbilical cord sampling and umbilical vein administration if hydrops is present). Most drug therapy is given to the mother, with subsequent placental passage to the fetus.

[†] Detailed fetal ultrasonography is needed to detect other anomalies; karyotype is also indicated.

[‡] EXIT permits surgery and other procedures.

EXIT, Ex utero intrapartum treatment; IVIG, intravenous immune globulin; (?), possible but not proved efficacy.

Aneuploidy screening is offered to pregnant women in the first trimester or at midgestation to evaluate the risk for common aneuploidies such as Down syndrome (trisomy 21), trisomy 18, trisomy 13, and congenital malformations (e.g., abdominal wall or neural tube defects) known to cause elevations of various markers. A combination of these biochemical markers (including AFP, inhibin A, estriol, pregnancy-associated plasma protein A, β–human chorionic gonadotropin [hCG]) and US increases the positive predictive value (PPV) of these screening tests. Fetal DNA in maternal plasma and fetal cells circulating in maternal blood are potential noninvasive sources of material for prenatal genetic testing. This testing, however, is not diagnostic, and a positive test requires either amniocentesis or postnatal analysis to confirm the diagnosis. Nonetheless, fetal karyotyping by analysis of fetal DNA in maternal plasma is another screening test that is very sensitive for the detection of Down syndrome, with a higher PPV than any other prenatal screening test for Down syndrome. Currently, however, the use of this technology is only advocated in pregnancies deemed at high risk for aneuploidy.

115.7

Treatment and Prevention of Fetal Disease

Kristen R. Suhrie, Sammy M. Tabbah

See also Chapter 116 .

Management of a fetal disease depends on coordinated advances in diagnostic accuracy and knowledge of the disease's natural history; an understanding of fetal nutrition, pharmacology, immunology, and pathophysiology; the availability of specific active drugs that cross the placenta; and therapeutic procedures. Progress in providing specific treatments for accurately diagnosed diseases has improved with the advent of real-time ultrasonography, amniocentesis, and cordocentesis (see Tables 115.1 and 115.8).

The incidence of sensitization of Rh-negative women by Rh-positive fetuses has been reduced by prophylactic administration of Rh(D) immunoglobulin to mothers early in pregnancy and after each delivery or abortion, thus reducing the frequency of hemolytic disease in their subsequent offspring. **Fetal erythroblastosis** (see Chapter 124.2) may be accurately detected by fetal Doppler assessment of the peak systolic velocity of the middle cerebral artery and treated with intrauterine transfusions of packed Rh-negative blood cells via the intraperitoneal or, more often, intraumbilical vein approach.

Pharmacologic approaches to fetal immaturity mostly revolve around the administration of antenatal corticosteroids to the mother to promote fetal production of surfactant with a resultant decrease in the incidence of **respiratory distress syndrome** (see Chapter 122.3). Tocolytic agents have been demonstrated to prolong pregnancy to allow the administration of antenatal corticosteroids (48 hr); however, there is no proven benefit beyond this timeframe. Maternal administration of magnesium sulfate for fetal/neonatal neuroprotection is recommended in pregnancies deemed to be at risk of imminent delivery before 32 wk gestation in light of evidence demonstrating a reduction in frequency of cerebral palsy compared to those who did not receive this treatment.

Management of definitively diagnosed fetal genetic disease or congenital anomalies consists of multidisciplinary parental counseling. Rarely, high-dose **vitamin therapy** for a responsive inborn error of metabolism (e.g., biotin-dependent disorders) or fetal transfusion (with red blood cells or platelets) may be indicated. **Fetal surgery** is well-established treatment for certain conditions but remains a largely experimental approach to therapy for other conditions and is available only in a few, highly specialized perinatal centers (see Table 115.8 and Chapter 116). The nature of the defect and its consequences must be considered, as well as ethical implications for the fetus and the parents. **Termination of pregnancy** is also an option that should be discussed during the initial phases of counseling.

Folic acid supplementation decreases the incidence and recurrence of NTDs. Because the neural tube closes within the 1st 28 days of conception, periconceptional supplementation is needed for prevention. It is recommended that women without a prior history of a NTD ingest 400 µg/day of folic acid throughout their reproductive years. Women with a history of a prior pregnancy complicated by an NTD or a first-degree relative with an NTD should have preconceptional counseling and should ingest 4 mg/day of supplemental folic acid beginning at least 1 mo before conception. Fortification of cereal grain flour with folic acid is established policy in the United States and some other countries. The optimal concentration of folic acid in enriched grains is somewhat controversial. The incidence of NTD in the United States and other countries has decreased significantly since these public health initiatives were implemented. Use of some antiepileptic drugs (valproate, carbamazepine) during pregnancy is associated with an increased risk of NTD. Women taking these medications should ingest 1-5 mg of folic acid daily in the preconception period.

CHAPTER 116

Fetal Intervention and Surgery

Paul S. Kingma

Numerous diagnoses have been evaluated for the possibility of fetal intervention (Tables 116.1 and 116.2). Some have proved beneficial to the developing infant, some have been abandoned, and some are still under investigation.

Table 116.1

Fetal Diagnoses Evaluated and Treated in Fetal Centers

Amniotic band syndrome (ABS)
Anomalies in monochorionic twins
Aortic stenosis
Arachnoid cyst
Bladder exstrophy
Bladder outlet obstruction
Bronchopulmonary sequestration (BPS)
Cervical teratoma
Cloaca
Cloaca exstrophy
Complete heart block
Congenital pulmonary airway malformation (CPAM)
Congenital diaphragmatic hernia (CDH)
Congenital high airway obstruction syndrome (CHAOS)
EXIT to airway procedure for CHAOS
Conjoined twins
Dandy-Walker malformation
Duodenal atresia
Encephalocele
Enteric duplicational atresia
Esophageal atresia
Gastroschisis
Hydrocephalus
Hydronephrosis
Hypoplastic left heart syndrome (HLHS)
Imperforate anus
Intraabdominal cyst
Lymphangioma

Mediastinal teratoma
Myelomeningocele, spina bifida
Neuroblastoma
Obstructive uropathy
Omphalocele
Pentalogy of Cantrell
Pericardial teratoma
Pleural effusions
Pulmonary agenesis
Pulmonary atresia with intact ventricular septum
Sacrococcygeal teratoma (SCT)
Twin reversed arterial perfusion (TRAP) sequence
Twin-twin transfusion syndrome (TTTS)
Vein of Galen aneurysm

EXIT, Ex utero intrapartum treatment.

Table 116.2

Indications and Rationales for in Utero Surgery on the Fetus, Placenta, Cord, or Membranes

FETAL SURGERY	PATHOPHYSIOLOGY	RATIONALE FOR IN UTERO INTERVENTION
SURGERY ON THE FETUS		
1. Congenital diaphragmatic hernia	Pulmonary hypoplasia and anatomic substrate for pulmonary hypertension	Reversal of pulmonary hypoplasia and reduced degree of pulmonary hypertension; repair of actual defect delayed until after birth
2. Lower urinary tract obstruction	Progressive renal damage due to obstructive uropathy Pulmonary hypoplasia due to oligohydramnios	Prevention of renal failure and pulmonary hypoplasia by anatomic correction or urinary deviation
3. Sacrococcygeal teratoma	High-output cardiac failure due to AV shunting and/or bleeding Direct anatomic effects of the tumoral mass Polyhydramnios-related preterm labor	Reduction of functional impact of tumor by ablation of tumor or (part of) its vasculature Reduction of anatomic effects by drainage of cysts or bladder Amnioreduction preventing obstetric complications
4. Thoracic space-occupying lesions	Pulmonary hypoplasia (space-occupying mass) Hydrops due to impaired venous return (mediastinal compression)	Creation of space for lung development Reversal of the process of cardiac failure
5. Neural tube defects	Damage to exposed neural tube Chronic CSF leak, leading to Arnold-Chiari malformation and hydrocephalus	Prevention of exposure of the spinal cord to amniotic fluid; restoration of CSF pressure correcting Arnold-Chiari malformation
6. Cardiac malformations	Critical lesions causing irreversible hypoplasia or damage to developing heart	Reversal of process by anatomic correction of restrictive pathology
SURGERY ON THE PLACENTA, CORD, OR MEMBRANES		
7. Chorioangioma	High-output cardiac failure due to AV	Reversal of process of cardiac failure

	shunting Effects of polyhydramnios	and hydrops fetoplacentalis by ablation or reduction of flow
8. Amniotic bands	Progressive constrictions causing irreversible neurologic or vascular damage	Prevention of amniotic band syndrome leading to deformities and function loss
9. Abnormal monochorionic twinning: twin-to-twin transfusion; fetus acardiacus, and discordant anomalies	Intertwin transfusion leading to oligopolyhydramnios sequence, hemodynamic changes; preterm labor, and rupture of membranes; in utero damage to brain, heart, or other organs In utero fetal death may cause damage to co-twin. Cardiac failure of pump twin and consequences of polyhydramnios Serious anomaly raising the question of termination of pregnancy Selective fetocide	Arrest of intertwin transfusion; prevention/reversal of cardiac failure and/or neurologic damage, including at in utero death; prolongation of gestation Selective fetocide to arrest parasitic relationship, to prevent consequences of in utero fetal death, and to avoid termination of entire pregnancy

AV, Arteriovenous; CSF, cerebrospinal fluid.

From Deprest J, Hodges R, Gratacos E, Lewi L: Invasive fetal therapy. In Creasy RK, Resnick R, Iams JD, et al, editors: *Creasy & Resnik's maternal-fetal medicine,* ed 7, Philadelphia, 2014, Elsevier (Table 35-1).

Fetal Therapy Ethics

With the development of advanced fetal ultrasound (US), fetal MRI, and fetal echocardiography, the ability to accurately diagnose fetal disease has improved substantially over the past 3 decades. There have also been advances in maternal anesthesia and tocolysis, reduction in maternal morbidity, development of fetal surgery–specific equipment, improved clinical expertise of the fetal care team, and construction of state–of-the-art fetal treatment centers. Fetal surgery remains controversial, however, and every discussion of fetal surgery must include a careful consideration of the ethical conflicts inherit to these procedures.

Unlike most surgical procedures, fetal surgery must consider 2 patients simultaneously, balancing the potential risks and benefits to the fetus with those to the mother during the current and future pregnancies. The **International Fetal Medicine and Surgery Society** (IFMSS) established a consensus statement on fetal surgery, as follows:

1. A fetal surgery candidate should be a singleton with no other abnormalities observed on level II ultrasound, karyotype (by amniocentesis), α-fetoprotein (AFP) level or viral cultures.
2. The disease process must not be so severe that the fetus cannot be saved

and also not so mild that the infant will do well with postnatal therapy.

3. The family must be fully counseled and understand the risks and benefits of fetal surgery, and they must agree to long-term follow-up to track efficacy of the fetal intervention.
4. A multidisciplinary team must concur that the disease process is fatal without intervention, that the family understands the risks and benefits, and that the fetal intervention is appropriate.

Obstructive Uropathy

Obstructive uropathy is most frequently caused by **posterior urethral valves** (PUV) but can be caused by a variety of other defects, including urethral atresia, persistent cloaca, caudal regression, and megacystis–microcolon–intestinal hypoperistalsis syndrome (see Chapters 555 and 556). Obstructive uropathy usually presents on fetal US with an enlarged bladder, bilateral hydroureteronephrosis, and oligohydramnios. Mild forms of obstructive uropathy may lead to minimal short- or long-term clinical sequelae. However, the lack of fetal urine output and resulting oligohydramnios or anhydramnios in more severe forms can cause significant **pulmonary hypoplasia** , which is associated with death shortly after delivery in >80% of infants. Pulmonary survivors are still subject to high mortality and chronic morbidity resulting from renal dysplasia, renal failure, and the need for chronic renal replacement therapy.

The primary objective of fetal intervention in fetuses with obstructive uropathy is *restoration of amniotic fluid volume to prevent pulmonary hypoplasia.* Although prevention of ongoing renal injury is also desired, the efficacy of fetal intervention in achieving this goal is uncertain. Several studies have attempted to use fetal urine evaluation to predict renal outcome in these patients, but the reliability of these markers has been disappointing due to the influence of gestational age on many of these markers. Therefore, fetal intervention for obstructive uropathy is currently limited to fetuses in whom the obstruction is sufficient to cause oligohydramnios or anhydramnios.

For fetuses who still have adequate renal function and are capable of producing urine, treatment options include vesicoamniotic shunting, valve ablation via cystoscopy, and vesicostomy. **Vesicoamniotic shunting** is the most common and involves percutaneous, US-guided placement of a double-pigtailed shunt from the fetal bladder to the amniotic space, allowing decompression of the obstructed bladder and restoration of the amniotic fluid volume (Fig. 116.1).

Although simple in concept, bladder decompression may not always occur, and many catheters will become dislodged as the fetus develops; a fetus typically requires 3 catheter replacements before completion of pregnancy. Vesicoamniotic shunting may improve perinatal survival, but at the expense of poor long-term renal function.

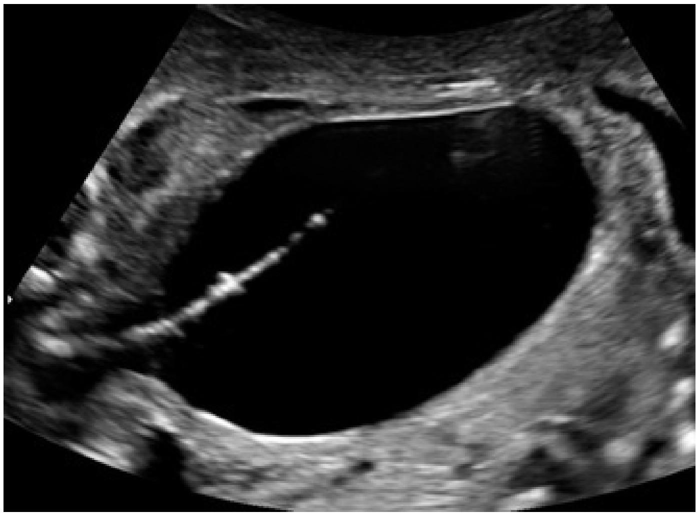

FIG. 116.1 Ultrasound image showing fetoscopic placement of a transurethral vesicoamniotic shunt in a patient with posterior urethral valves. (Courtesy of Dr. Foong Lim, Cincinnati Fetal Center at Cincinnati Children's Hospital Medical Center.)

Fetal cystoscopy is more technically challenging than vesicoamniotic shunt placement, more invasive, and requires more sedation, but this option holds some important advantages. Cystoscopy allows for direct visualization of the obstruction and does not require amnioinfusion. Moreover, when the obstruction is visualized and the diagnosis of PUV confirmed, the valves can be treated, restoring urine flow to the amniotic space and eliminating the need for repeated fetal interventions in most patients. Creation of a **vesicostomy** (direct opening from bladder through fetal abdominal wall) by open fetal surgery has improved perinatal survival (Fig. 116.2). However, the current dataset evaluating this approach is still limited, and direct comparisons to shunting suggest no significant difference between these interventions.

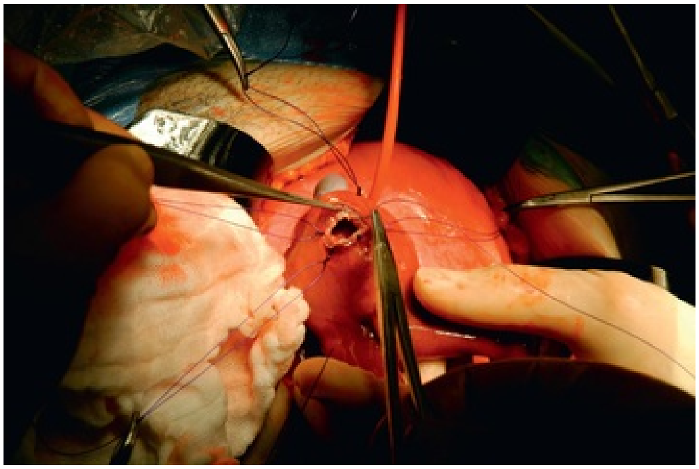

FIG. 116.2 Creation of a fetal vesicostomy. The uterine opening is stapled to prevent bleeding, and a catheter is inserted to replace amniotic fluid and maintain uterine volume. The fetus is positioned with the legs to the lower part of the field and the umbilical cord to the upper part of the field. A vesicostomy is created through the bladder and the abdominal wall to allow drainage of the obstructed bladder and restoration of amniotic fluid volume. (Courtesy of Dr. Foong Lim, Cincinnati Fetal Center at Cincinnati Children's Hospital Medical Center.)

Nonobstructive Renal Disease

Nonobstructive fetal renal disease can result from renal hypoplasia/dysplasia and from genetic disease such as autosomal recessive polycystic kidney disease. Similar to obstructive uropathy, fetal therapy is focused on restoring amniotic fluid volume in patients with oligohydramnios or anhydramnios. However, restoration of amniotic fluid volume in nonobstructive renal disease requires external sources of amniotic fluid. Current treatment options include serial percutaneous amnioinfusion and infusion of fluid by amnioport. **Serial amnioinfusions** are less invasive as a single procedure, but most pregnancies will require weekly infusions to maintain adequate amniotic fluid volume. Amnioinfusion through an **amnioport** involves open surgical placement of a catheter into the amniotic space that is connected to an ex utero subcutaneous port. This allows repeated fluid infusion into the amniotic space. The amnioport is more challenging and invasive as an individual procedure but provides more reliable access to the amniotic space for the duration of the pregnancy. Small studies suggest both these procedures improve pulmonary outcomes and perinatal survival in infants with renal disease, but these infants will require dialysis and then renal transplant when the infant is large enough (2-3 yr of age).

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (**CDH**) is a defect in the fetal diaphragm causing herniation of the abdominal contents into the thorax and inhibition of fetal lung growth (see Chapter 122.10). CDH occurs in 1 in 3,000 births and can range from mild to severe. In mild cases of CDH, surgical repair of the diaphragm is typically performed in the 1st few days of life. Lungs in these infants are smaller than normal at birth, but as they grow, these patients can lead normal, active lives. In the severe cases of CDH infants experience severe pulmonary hypoplasia and pulmonary hypertension, requiring extracorporeal membrane oxygenation (ECMO) in the perinatal period. Mortality is high in severely affected infants, and survivors often have long-term respiratory, feeding, and neurodevelopmental problems.

Early attempts at fetal intervention for CDH used **in utero** surgical correction of the diaphragm defect in severe CDH infants. Survival rates were poor, with most infants dying during or shortly after the fetal surgery. Since significant complications during this procedure involved reduction of the incarcerated liver, a follow-up study compared **postnatal** repair to in utero repair that was limited to infants without liver herniation in the chest. The fetal repair group had more premature delivery (32 vs 38 wk gestation) without an improvement in survival (75% fetal repair vs 86% postnatal repair). Therefore, attempts at in utero repair of CDH have been abandoned.

Occlusion of the fetal trachea causes lung growth, and this approach was capable of dramatically improving lung growth in animal models of pulmonary hypoplasia. Several groups explored the use of fetal tracheal occlusion in CDH. The fetal surgical team in Philadelphia evaluated both open fetal tracheal ligation and endoscopic tracheal occlusion with an inflatable balloon. Open fetal tracheal ligation was quickly abandoned, with most patients dying from either complications associated with the procedure or shortly after delivery from respiratory failure caused by the lack of alveolar type II cell maturation and surfactant production in the hyperexpanded lungs. Endoscopic balloon tracheal occlusion was eventually evaluated in a larger trial. Survival was better than open fetal tracheal ligation but still not improved over control patients. Development of **fetoscopic balloon tracheal occlusion** in CDH led to the multicenter prospective randomized Tracheal Occlusion to Accelerate Lung Growth (**TOTAL**) study. In this trial the balloon was inserted at 27-30 wk and removed at 34 wk. This timing is based on the hypothesis that tracheal occlusion will promote lung expansion while removal of the balloon before delivery will promote alveolar type II cell maturation. Initial data suggest that this approach is associated with a high incidence of preterm delivery but a significant increase in survival. The use of fetoscopic tracheal occlusion in CDH therapy is gaining popularity, but this approach in both severe and moderate CDH is still under investigation.

Congenital Pulmonary Airway Malformation

Congenital pulmonary airway malformation (**CPAM**), previously referred to as *congenital cystic adenomatoid malformation* (CCAM), is caused by abnormal branching and hamartomatous growth of the terminal respiratory structures that results in cystic and adenomatoid malformations (see Chapter 423). Although rare, these remain the most common congenital lung lesion. CPAMs usually arise between 5 and 22 wk of gestation and continue to increase in size until around the 26th wk of pregnancy. If large enough, CPAM can cause significant pulmonary hypoplasia and in severe cases, hydrops fetalis. The size of the CPAM is tracked by CPAM volume ratio (**CVR**), an index that compares the volume of the CPAM to the fetal head circumference. Most studies indicate >95% survival in CPAM patients with no hydrops and CVR <1.6, with a much lower survival and greater risk for hydrops in patients with a CVR >1.6. Without intervention, CPAM with hydrops is uniformly fatal.

Open fetal **resection** of CPAM was considered one of the first clearly beneficial fetal surgeries. A less invasive option in fetal patients with CPAM composed of a large, dominant cyst is the insertion of a thoracoamniotic shunt into the dominant cyst. This decreases CPAM size, allowing lung growth and reducing risk of hydrops. An alternative surgical approach involving resection of the CPAM at delivery while the infant remains on placental support via an **ex utero intrapartum therapy (EXIT)** procedure has also demonstrated improved survival in a select group of patients.

Patients (in utero) receiving corticosteroids experience improved survival compared with those receiving open fetal resection. Survival rates approach 100% in high-risk CPAM (CVR >1.6) treated with steroids before the onset of hydrops and 50% in patients who have developed hydrops. Therefore the current approach to fetal therapy for CPAM has been away from open fetal resection and toward single or multiple courses of antenatal corticosteroids in fetuses with CVR >1.6.

Myelomeningocele

Before the introduction of fetal repair of **myelomeningocele (MMC)** , fetal surgery was limited to diagnoses considered fatal for the fetus or infant without intervention. However, a growing body of data suggests that the neurologic outcome in MMC is directly related to progressive injury from ongoing damage to the exposed spinal cord during pregnancy (see Chapter 609.3). Controversy remained as to whether the maternal and fetal risks of fetal repair should be accepted when the goal was to reduce postnatal morbidity rather than to improve survival.

The observation in early studies that patients receiving open fetal MMC repair were less likely to require **ventriculoperitoneal (VP) shunt** prompted the prospective randomized trial of prenatal vs postnatal MMC management (MOMS) (Fig. 116.3). The study was closed to enrollment in 2010 after 183 patients were randomized and the data safety monitoring board determined a clear advantage for prenatal surgery. The MOMS trial demonstrated a significant reduction in the need for VP shunt in the fetal repair group (40% vs 82% in postnatal repair group). The fetal repair group had an improved composite score for mental development and motor function at 30 mo, but also an increased risk of preterm delivery and uterine dehiscence. The average gestational age at delivery in the fetal repair group was 34 wk, with 10% delivering at <30 wk, compared to 37 wk and no infants <30 wk in the postnatal repair group.

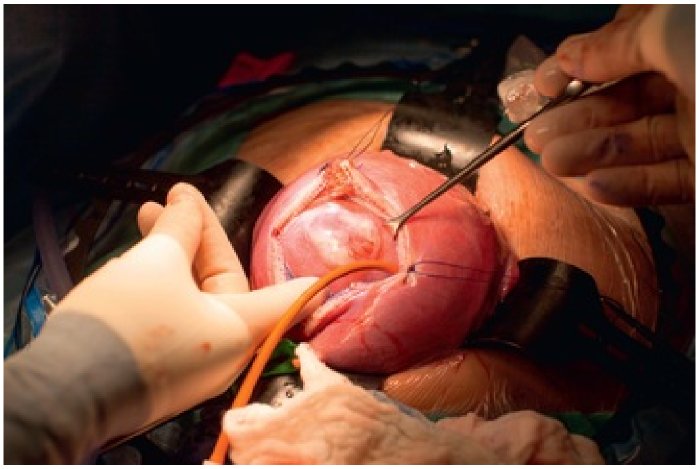

FIG. 116.3 Fetus during open repair of myelomeningocele. The uterine opening is stapled to prevent bleeding, and a catheter is inserted to replace amniotic fluid and maintain uterine volume. The myelomeningocele is exposed through the uterine opening and repaired. (Courtesy of Dr. Foong Lim, Cincinnati Fetal Center at Cincinnati Children's Hospital Medical Center.)

Open fetal repair of MMC has been an important advance but the risk of prematurity significantly decreases the benefit of this procedure. In theory, the less invasive fetoscopic MMC repair approach, which is being developed at a limited number of centers, should reduce maternal morbidity and prematurity rates associated with open fetal MMC repair (▶ Video 116.1).

Other Indications

Antenatal intervention for cardiac defects, such as aortic stenosis, pulmonic stenosis, and hypoplastic left heart syndrome (HLHS), have been used to dilate, with balloon valvuloplasty, stenotic valves (aortic stenosis) to prevent further development of HLHS (creating biventricular physiology) (Fig. 116.4) (see Chapter 458.10).

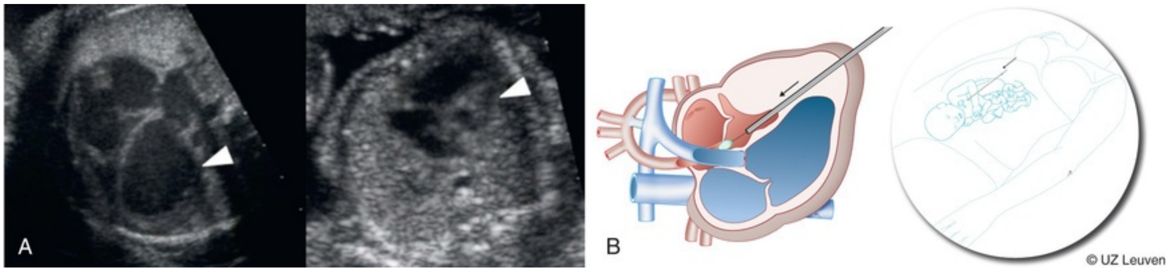

FIG. 116.4 **A,** Ultrasound image *(right panel)* is a cross section at the level of the fetal chest, demonstrating the 4-chamber view in a fetus with aortic

stenosis. Notice that the left ventricle *(arrowhead)* is dilated. Dilation occurs before the development of hypoplasia, which can be seen *(arrowhead)* in another fetus *(left panel)* . **B,** Schematic representation of percutaneous valvuloplasty, in this case of the left ventricular outlet tract. Fetal Centers

The value of fetal centers extends beyond fetal surgery. Often, families will present to a fetal center with a newly discovered diagnosis and little understanding of what the diagnosis means for their baby. **Prenatal counseling** by the fetal team can provide comfort to the family by helping them understand the diagnosis and treatment options and by developing a management plan that may include fetal surgery. Some plans may call for enhanced monitoring of the fetus and mother, followed by complex deliveries involving multidisciplinary delivery teams and specialized equipment, as required for EXIT to ECMO, EXIT to airway, EXIT to tumor resection, delivery to cardiac catheterization, and procedures on placental support. Other plans may focus on postnatal therapy.

Not all severely affected fetuses have available therapies in utero or after birth. In these lethal situations, fetal care planning will provide support for the family and a plan for delivery room or nursery palliative care (Table 116.3) (see Chapter 7).

Table 116.3

Selection of Patients for Fetal Repair

LEVEL OF CERTAINTY	DIAGNOSIS
DIAGNOSTIC CERTAINTY/PROGNOSTIC CERTAINTY	
Genetic problems	Trisomy 13, 15, or 18
	Triploidy

Central nervous system abnormalities	Anencephaly/acrania
	Holoprosencephaly
	Large encephaloceles
Heart problems	Acardia
	Inoperable heart anomalies
Kidney problems	Potter syndrome/renal agenesis
	Multicystic/dysplastic kidneys
	Polycystic kidney disease
DIAGNOSTIC UNCERTAINTY/PROGNOSTIC CERTAINTY	
Genetic problems	Thanatophoric dwarfism or lethal forms of osteogenesis imperfecta
Early oligo/anhydramnios and pulmonary hypoplasia	Potter syndrome with unknown etiology
Central nervous system abnormalities	Hydranencephaly
	Congenital severe hydrocephalus with absent or minimal brain growth
Prematurity	<23 wk gestation
PROGNOSTIC UNCERTAINTY/BEST INTEREST	
Genetic problems	Errors of metabolism that are expected to be lethal even with available therapy
Mid oligo/anhydramnios	Renal failure requiring dialysis
Central nervous system abnormalities	Complex or severe cases of meningomyelocele
	Neurodegenerative diseases, such as spinal muscular atrophy
Heart problems	Some cases of hypoplastic left heart syndrome
	Pentalogy of Cantrell (ectopia cordis)
Other structural anomalies	Some cases of giant omphalocele
	Severe congenital diaphragmatic hernia with hypoplastic lungs
	Idiopathic nonimmune hydrops
	Inoperable conjoined twins
	Multiple severe anomalies
Prematurity	23-24 wk gestation

CHAPTER 117

The High-Risk Infant

Jennifer M. Brady, Maria E. Barnes-Davis, Brenda B. Poindexter

The term *high-risk infant* designates an infant at greater risk for neonatal morbidity and mortality; many factors can contribute to an infant being high risk (Table 117.1). High-risk infants are categorized into 4 main groups: the preterm infant, infants with special health care needs or dependence on technology, infants at risk because of family issues, and infants with anticipated early death.

Table 117.1

Factors in Considering Infants as High Risk for Morbidity or Mortality in the Neonatal Period

MATERNAL DEMOGRAPHIC/SOCIAL FACTORS
Maternal age <16 yr or >40 yr
Illicit drug, alcohol, cigarette use
Poverty
Unmarried
Emotional or physical stress
MATERNAL MEDICAL HISTORY
Genetic disorders
Diabetes mellitus
Hypertension
Asymptomatic bacteriuria
Rheumatologic illness (systemic lupus erythematosus)
Immune-mediated diseases (IgG crossing placenta)
Long-term medication (see Chapters 115.4 and 115.5)
PREVIOUS PREGNANCY
Intrauterine fetal demise
Neonatal death
Prematurity
Intrauterine growth restriction
Congenital malformation
Incompetent cervix
Blood group sensitization, neonatal jaundice
Neonatal thrombocytopenia
Hydrops

Inborn errors of metabolism

PRESENT PREGNANCY

Vaginal bleeding (abruptio placentae, placenta previa)
Sexually transmitted infections (colonization: herpes simplex, group B streptococcus, chlamydia, syphilis, hepatitis B, HIV)
Multiple gestation
Preeclampsia
Premature rupture of membranes
Short interpregnancy time
Poly-/oligohydramnios
Acute medical or surgical illness
Inadequate prenatal care
Familial or acquired hypercoagulable states
Abnormal fetal ultrasonographic findings
Treatment of infertility

LABOR AND DELIVERY

Premature labor (<37 wk)
Postdates pregnancy (≥42 wk)
Fetal distress
Immature lecithin/sphingomyelin ratio; absence of phosphatidylglycerol
Breech presentation
Meconium-stained fluid
Nuchal cord
Cesarean delivery
Forceps delivery
Apgar score <4 at 5 min

NEONATE

Birthweight <2,500 g or >4,000 g
Birth <37 wk or ≥42 wk of gestation
Small or large for gestational age
Respiratory distress, cyanosis
Congenital malformation
Pallor, plethora, petechiae

All high-risk infants require closer evaluation and/or treatment by experienced physicians and nurses. This often starts at delivery and continues through a neonatal intensive care unit (NICU) stay (see Chapter 121). Regionalized care for infants is based on the acuity of care that can be provided at hospitals with different levels of care and whether transport should be undertaken (see Chapter 118). It is important to note that additional care does not stop at time of NICU discharge, and that many high-risk infants also benefit from additional resources and follow-up after discharge from the hospital (see Chapter 117.5).

Approximately 15 million infants are born preterm (before 37 wk gestational age) each year worldwide, accounting for approximately 1 in every 10 babies born, and the overwhelming majority of high-risk infants. The World Health Organization (WHO) defines infants born before 28 wk gestational age as *extremely preterm* infants, infants born between 28 and $31\frac{6}{7}$ wk as *very preterm*, and infants born between 32 and $36\frac{6}{7}$ weeks as *moderate to late preterm* infants.

Risk of both morbidity and mortality increases with earlier gestational age. Gestational age, birthweight, and gender are all important factors that impact neonatal mortality (Fig. 117.1). The **highest risk** of neonatal and infant mortality occurs in infants with birthweight <1,000 g and/or with gestational age <28 wk. The **lowest risk** of neonatal mortality occurs in infants with birthweight of 3,000-4,000 g and a gestational age of 39-41 wk. As birthweight increases from 400 to 3,000 g and gestational age increases from 23 to 39 wk, a logarithmic decrease in neonatal mortality occurs. Once birthweight exceeds 4000 g and/or gestational age exceeds 42 wk, the incidence of neonatal morbidities and mortality increases.

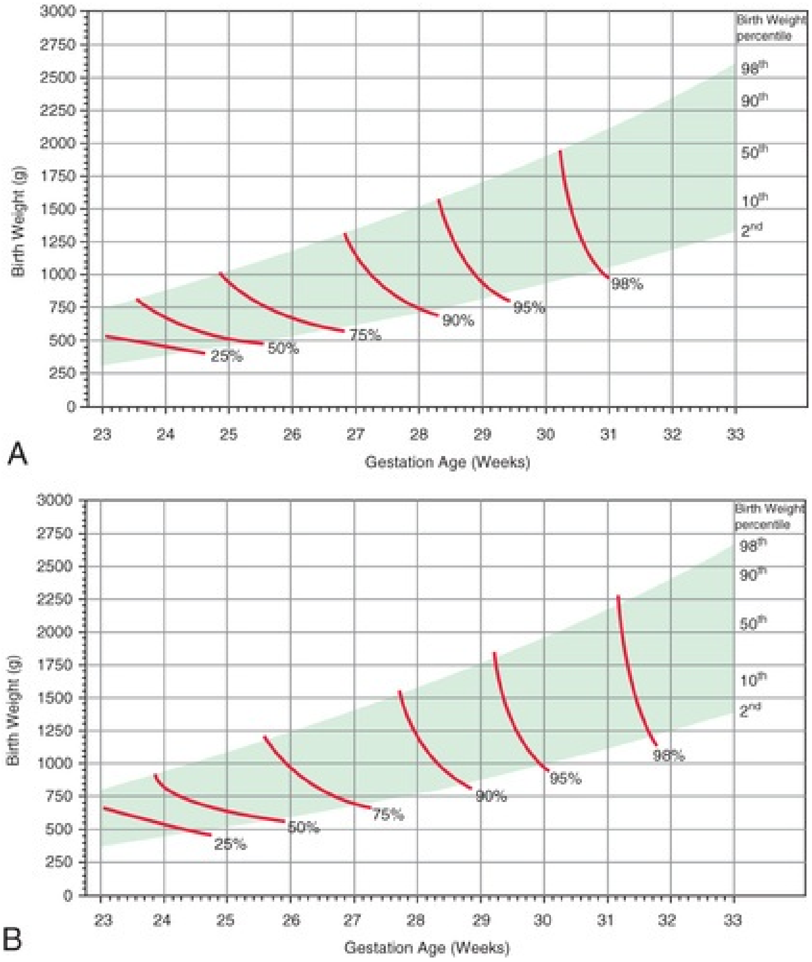

FIG. 117.1 Contour plot of predicted survival according to gestational age, birthweight, and gender. A, Female. B, Male. The contour lines join combinations of gestational age and birthweight of equal estimated probability of survival. Birthweight percentiles are shown for information. Data based on singleton infants born in the United Kingdom between January 2008 and December 2010 who survived to NICU admission. (From Manktelow BN, Seaton SE, Fields DJ, et al: Population-based estimates of in-unit

survival for very preterm infants, *Pediatrics* 131:e425–e432, 2013, Fig 2.)

Monozygotic vs Dizygotic Twins

Identifying twins as **monozygotic** or **dizygotic** is useful in determining the relative influence of heredity and environment on human development and disease. The previous assumption that twins not of the same sex are dizygotic can no longer be held as true. Sex discordance, placentation, and determination of amnionicity and chorionicity are not reliable ways of determining zygosity. Detailed blood typing, gene analysis, or tissue (human leukocyte antigen) typing can be used for zygosity testing (an exception being blood typing in cases of **chimeric** twins, where one or both twins contain distinct cell lines from multiple zygotes). Physical and cognitive differences may still exist between monozygotic twins because of other factors. The in utero environment may have been different. Additionally, differences may exist in the mitochondrial genome, in posttranslational gene product modification, and in the epigenetic modification of nuclear genes in response to environmental factors.

Examination of the Placenta

If the placentas are separate, twins are **dichorionic** , but not necessarily dizygotic. One third of monozygotic twins are **dichorionic** and **diamnionic.** An apparently single placenta may be present with either monozygotic or dizygotic twins, but inspection of a dizygotic placenta usually reveals that each twin has a separate chorion that crosses the placenta between the attachments of the cords and 2 amnions. Separate or fused dichorionic placentas may be disproportionate in size. The fetus attached to the smaller placenta or the smaller portion of the placenta is usually smaller than its twin or is malformed. **Monochorionic** twins are usually **diamnionic** , and the placenta is usually a single mass.

Incidence

The incidence of **spontaneous twinning** is highest among blacks and East Indians, followed by northern European whites, and is lowest in the Asian races. Differences in the incidence of twins worldwide mainly involve dizygotic twins. The incidence of monozygotic twins (3-5 per 1,000) is unaffected by racial or familial factors. Until recently, monozygotic twinning rates remained stable across continents and cultures. In 2014 the U.S. final natality report recorded a twin rate of 33.9 per 1,000 live births, which was a new high for the nation.

Increases in monozygotic and dizygotic twinning have been associated with advanced maternal age (AMA) and the use of assisted reproductive technologies (ART). The rate of triplets and higher-order multiple births is 113.5 per 100,000 live births in the United States and continues to decline. The use of single-embryo transfer in ART has decreased the numbers of triplet births and higher-order multiples. However, a doubling of **monozygotic** twinning and an increase in atypical twinning have been reported. The incidence of **dizygotic** multifetal gestation is also increasing, attributed to treatment of infertility with ovarian stimulants (clomiphene, gonadotropins).

Etiology

Polyovular pregnancies are more frequent beyond the 2nd pregnancy, in older women, and in families with a history of dizygotic twins. They may result from simultaneous maturation of multiple ovarian follicles, but follicles containing 2 ova have also been described as a genetic trait leading to twin pregnancies. Twin-prone women have higher levels of gonadotropin. Polyovular pregnancies occur in many women treated for infertility.

The occurrence of monozygotic twins appears to be independent of heritable factors. The etiology of monozygotic twinning is unknown, but there are 2 prevailing theories. In the classic **fission theory** , twinning results from the splitting of a single conceptus, with the timing of splitting resulting in differing amnionicity and chorionicity (i.e., the earlier the fission occurs, the more likely the twins are to be diamniotic dichorionic) (Fig. 117.2). However, this theory fails to account for several forms of atypical twinning, including the occurrence of **diamniotic dichorionic monozygotic** twinning after single-embryo transfer in the late blastocyst state, phenotypically-discordant monozygotic twins, and asymmetrically attached conjoined twins. An alternate **fusion theory** of twinning has been proposed to account for this discrepancy, in which the inner cell masses of trophectoderm fuse after the initial 2-cell splitting stage (Fig. 117.3).

FIG. 117.2 Classical fission theory of twinning. *Dizygotic twins* result from 2 distinct fertilization events, with dichorionic diamniotic twins each developing to become a genetically distinct individual. *Monozygotic twins* result from postzygotic splitting of the product of a single fertilization event. Splitting on days 1-3 (up to the morula stage) results in dichorionic diamniotic twins, on days 3-8 (during which blastocyst hatching occurs) in monochorionic diamniotic twins, on days 8-13 in monochorionic monoamniotic twins. Dichorionic diamniotic
Monochorionic diamniotic
Monochorionic monoamniotic

FIG. 117.3 Fusion theory of monozygotic twinning. Splitting occurs at the postzygotic 2-cell stage, with each cell forming a distinct individual. If twin blastocysts hatch from the zona pellucida together, dichorionic diamniotic twins will result. If the 2 trophectoderms fuse before hatching and the inner cells masses are separated within the shared trophectoderm, monochorionic diamniotic twins will result. If the inner cell masses are fused and separated later, monochorionic monoamniotic twins will result. (Illustration copyright © LeventEfe, CMI. www.leventefe.com.au .)

Atypical Twinning

Conjoined twins (1 in 50,000 pregnancies and 1 in 250,000 live births) are obligate **monozygotes** . Theoretically, they result from later fission of a single zygote (10-14 days) or from fusion of 2 zygotes (as proposed for asymmetrically attached conjoined twins). The majority of conjoined twins are female. The prognosis for symmetrically conjoined twins depends on the possibility of surgical separation, which in turn depends on the extent to which vital organs are shared. The site of connections varies: thoracoomphalopagus (28% of conjoined twins), thoracopagus (18%), omphalopagus (10%), craniopagus (6%), and incomplete duplication (10%). The term *parasitic twin* has historically been used to describe the smaller and less completely developed member of a pair of conjoined twins; this *parasitic* twin has typically had embryonic demise but remains vascularized by the surviving *independent* twin (the **autocyte**). For asymmetrically attached conjoined twins in whom one twin is dependent on the cardiovascular system of the intact autocyte (**exoparasitic twins** , 1 in 1 million live births) survival of the autocyte depends on the feasibility of excising the *exoparasitic* twin. For **endoparasitic twins** (*fetus in fetu,* 1 in 500,000 live births) in whom one (or more) fetus exists as a benign mass in the autocyte, survival of the autocyte is unaffected.

Superfecundation, or fertilization of an ovum by an insemination that takes place after one ovum has already been fertilized, and **superfetation,** or fertilization and subsequent development of an embryo when a fetus is already present in the uterus, have been proposed as explanations for differences in size and appearance of certain twins at birth.

Complications

Problems of twin gestation include polyhydramnios, hyperemesis gravidarum, preeclampsia, premature rupture of membranes (PROM), vasa previa, velamentous insertion of the umbilical cord, abnormal presentation (breech), and premature labor. **Monoamniotic** twins have a high fatality rate because of obstruction of the circulation secondary to intertwining of the umbilical cords.

Compared with the 1st-born twin, the 2nd twin is at increased risk for respiratory distress syndrome and asphyxia. Twins are at risk for intrauterine growth restriction, twin-twin transfusion syndrome, and congenital anomalies, which occur predominantly in **monozygotic** twins. Anomalies are a result of compression *deformation* of the uterus from crowding (hip dislocation), vascular communication with embolization (ileal atresia, porencephaly, cutis aplasia) or without embolization (acardiac twin), and unknown factors (conjoined twins, anencephaly, meningomyelocele).

Twin Syndromes (TRAP, TTTS)

Placental vascular anastomoses occur with high frequency in **monochorionic** twins. In monochorionic placentas, the fetal vasculature is usually joined, sometimes in a very complex manner. They are usually balanced so that neither twin suffers. Artery-to-artery communications cross over placental veins, and when anastomoses are present, blood can readily be stroked from one fetal vascular bed to the other. Vein-to-vein communications are similarly recognized but are less common. A combination of artery-to-artery and vein-to-vein anastomoses is associated with the condition of **acardiac fetus** . This rare lethal anomaly (1 in 35,000) is secondary to the **twin reversed arterial perfusion (TRAP) syndrome** . In utero radiofrequency or laser ablation of the anastomosis or cord occlusion can be used to treat heart failure in the surviving twin. However, death of the autocyte is reported in up to 75% of cases. In rare cases, one umbilical cord may arise from the other after leaving the placenta, and the twin attached to the secondary cord usually is malformed or dies in utero.

In **twin-twin transfusion syndrome (TTTS)** , an artery from one twin acutely or chronically delivers blood that is drained into the vein of the other. The latter develops polyhydramnios, plethoric and large for dates, and the former has oligohydramnios, anemic and small (Fig. 117.4). TTTS is more common in monozygotic twins and affects up to 30% of monochorionic twins. Maternal polyhydramnios in a twin pregnancy suggests TTTS. Anticipating this possibility by preparing to transfuse the donor twin or bleed the recipient twin may be lifesaving. Death of the donor twin in utero may result in generalized fibrin thrombi in the smaller arterioles of the recipient twin, possibly as the result of transfusion of thromboplastin-rich blood from the macerating donor fetus. Disseminated intravascular coagulation (DIC) may develop in the surviving twin. Table 117.2 lists the more frequent changes associated with a large shunt. **Treatment** of this highly lethal problem includes maternal digoxin, aggressive amnioreduction for polyhydramnios, selective twin termination, and more often, laser or fetoscopic ablation of anastomosis (Fig. 117.5).

After identification and coagulation of each individual anastomosis, the complete vascular equator is coagulated from one placental margin to the other. (From Slaghekke F, Lopriore E, Lewi L, et al: Fetoscopic laser coagulation of the vascular equator versus selective coagulation for twin-to-twin transfusion syndrome: an open-label randomized controlled trial, *Lancet* 383:2144–2150, 2014, Fig 3.)**

Diagnosis

A prenatal diagnosis of pregnancy with twins is suggested by a uterine size that is greater than that expected for gestational age, auscultation of 2 fetal hearts, and elevated maternal serum α-fetoprotein (AFP) or human chorionic gonadotropin (hCG) levels. It is confirmed by ultrasonography. Physical examination of twins is necessary but not sufficient to determine zygosity of twins. In the event that congenital anomalies are present or there are transfusion or transplantation considerations, genetic testing of zygosity should be performed. While noninvasive prenatal testing (NIPT) is becoming more common, the results should be interpreted with caution in multiple-gestation pregnancies until more findings are better established.

Prognosis

Most twins are born prematurely, and maternal complications of pregnancy are more common than with single pregnancies. The risk for twins is most often associated with twin-twin transfusion, ART, and early-onset discordant growth. Because most twins are premature, their overall mortality is higher than that of single-birth infants. The perinatal mortality of twins is about 4 times that of singletons, with **monochorionic** twins being particularly at risk. **Monoamnionic** twins have an increased likelihood of cord entanglement, which may lead to asphyxia. Twins are at greater risk for congenital malformations, with up to 25% of monozygotic twins being affected. Theoretically, the 2nd twin is more subject to anoxia than the 1st because the placenta may separate after birth of the 1st twin and before birth of the 2nd. In addition, delivery of the 2nd twin may be difficult because it may be in an abnormal presentation (breech, entangled), uterine tone may be decreased, or the cervix may begin to close after the 1st twin's birth.

Triplet or higher-order births are associated with an increased risk of death or neurodevelopmental impairment compared with extremely-low-birthweight (ELBW) singleton and twin infants after controlling for gestational age. The mortality for multiple gestations with ≥4 fetuses is excessively high for each fetus. Because of this poor prognosis, selective fetal reduction has been offered as a treatment option. **Monozygotic** twins have an increased risk of one twin dying in utero. The surviving twin has a greater risk for cerebral palsy and other neurodevelopmental sequelae.

Treatment

Prenatal diagnosis enables the obstetrician and pediatrician to anticipate the birth of infants who are at high risk because of twinning. The risk of multiple-gestation pregnancies using ART may be reduced by elective single-embryo transfers. In addition, elective delivery of twins at 37 wk (or earlier for **monochorionic** , **monoamniotic** twins) reduces the complication rate for the fetuses and the mother. Furthermore, in twin pregnancies between 32 and 39 wk of gestation, planned vaginal delivery is preferred if the 1st twin is in the cephalic presentation. Close observation and attendance by a pediatric team are indicated in the immediate neonatal period so that prompt treatment of asphyxia or fetal transfusion syndrome can be initiated. The decision to perform an immediate blood transfusion in a severely anemic “donor twin” or a partial exchange transfusion of a “recipient twin” must be based on clinical judgment.

Ballard scoring system
extremely low birthweight

extremely low gestational age newborn
extremely preterm
kangaroo care
low birthweight
neutral thermal environment
very low birthweight

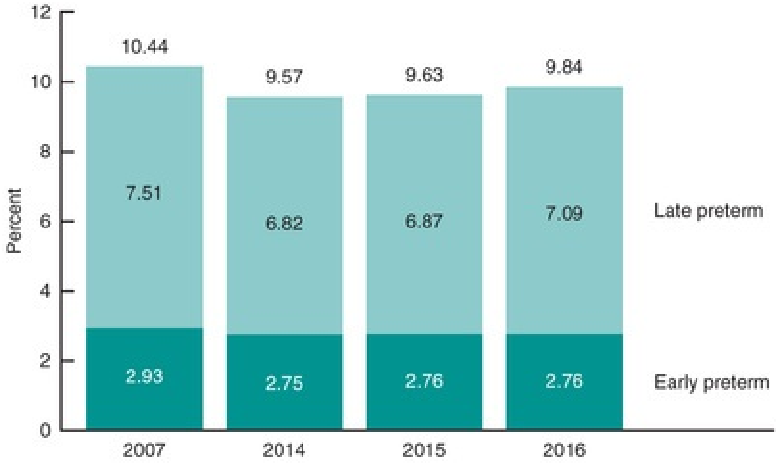
Traditionally, a delivery date is determined 280 days after the last menstrual period (LMP). However, only 4% of pregnant women actually deliver at 280 days, and only 70% deliver within 10 days of the estimated delivery date.

Infants born before 37 wk from the 1st day of the LMP are termed *premature* by WHO. Infants born before 28 wk gestation are **extremely preterm,** also referred to as **extremely low gestational age newborns (ELGANs)** ; whereas infants born between 28 and $31\frac{6}{7}$ are **very preterm** . Moderate and late preterm infants (born between 32 and $36\frac{6}{7}$ wk gestation) are discussed in Chapter 117.3 .

In addition to classification by gestational age, classification is also based on birthweight. **Extremely low birthweight (ELBW)** is used to describe infants with a birthweight <1000 g, **very low birthweight (VLBW)** describes infants <1500 g, and **low birthweight (LBW)** describes infants <2500 g at birth. Birthweight in general is a proxy for gestational age, but in the cases of intrauterine growth restriction (IUGR) and small-for-gestational-age (SGA) infants, birthweight can sometimes be misleading for true gestational age (see Chapter 117.4).

Incidence

Preterm birth , or birth before 37 wk of gestation, is fairly common. Worldwide, approximately 15 million preterm births occur annually. In the United States, approximately 10% of all births are preterm. After a prolonged period of increasing rates of preterm birth, preterm births in the United States peaked at 10.44% in 2007. From 2007 until 2014, a slow but steady decline occurred in preterm births, to 9.57% in 2014. Preliminary data show that preterm births have slightly increased since 2014, with 9.84% of all U.S. births being preterm in 2016 and a disproportionate increase in late preterm births (Fig. 117.6). Of preterm births in 2016, the majority were late preterm infants, approximately 72% of preterm births, with the remaining 28% being extremely or early preterm.



NOTES: Gestational age is measured in completed weeks based on the obstetric estimate. Early preterm is births before 32 weeks; late preterm is births at 34–36 weeks. Figures may not add to totals due to rounding.
SOURCE: NCHS, National Vital Statistics System.

FIG. 117.6 **Preterm birth rates in the United States in 2007, 2014, 2015, and 2016 (provisional). There was a recent rise in preterm birth rate from 2014 to 2016. Preterm birth rate further divided into early preterm birth (birth <32 wk) and late preterm birth (birth at $34-36\frac{6}{7}$ wk). (From Hamilton BE, Martin JA, Osterman MJK, et al: Births: provisional data for 2016, *Vital Statistics Rapid Release* 2017; 1–21, Fig 4.)**

Etiology

Despite the frequency of preterm birth, it is often difficult to determine a specific cause. The etiology of preterm birth is multifactorial and involves complex interactions between fetal, placental, uterine, and maternal factors. In the setting of maternal or fetal conditions that prompt early delivery, as well as placental and uterine pathology, causes of preterm birth can sometimes be identified (Table 117.3).

Table 117.3

Identifiable Risk Factors for Preterm Birth

FETAL
Fetal distress
Multiple gestation
Erythroblastosis

Nonimmune hydrops

PLACENTAL

Placental dysfunction
Placenta previa
Placental abruption

UTERINE

Bicornuate uterus
Incompetent cervix (premature dilation)

MATERNAL

Previous preterm birth
Preeclampsia
Black race
Chronic medical illness (cyanotic heart disease, renal disease, thyroid disease)
Short interpregnancy interval
Infection (*Listeria monocytogenes,* group B streptococcus, urinary tract infection, bacterial vaginosis, chorioamnionitis)
Obesity
Drug abuse (cocaine)
Young or advanced maternal age

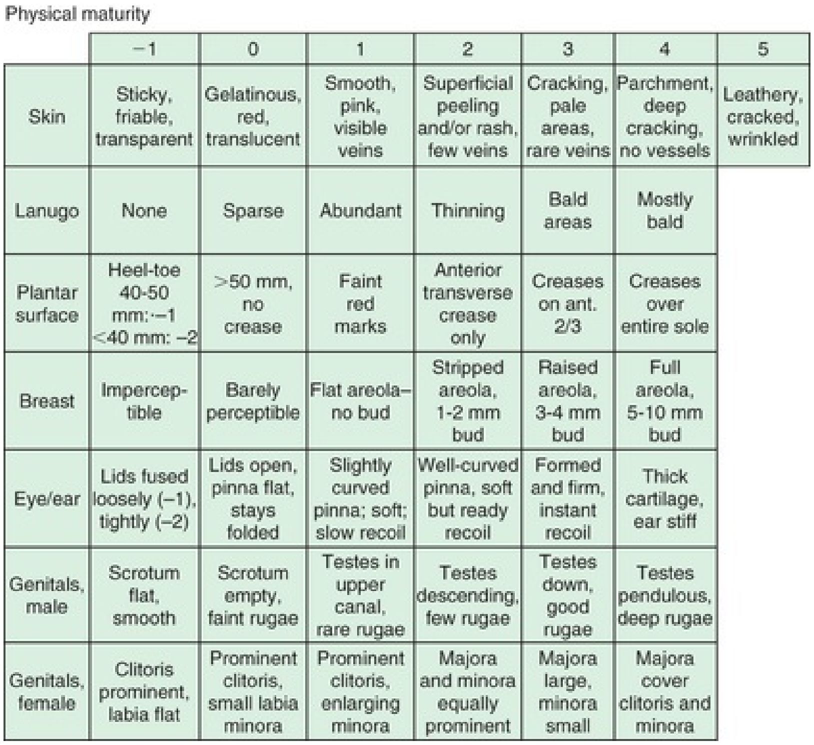
OTHER

Premature rupture of membranes
Polyhydramnios
Iatrogenic
Assisted reproductive technology
Trauma

However, most preterm births are *spontaneous* without an identifiable cause. Older maternal age, poorer maternal health, history of previous preterm delivery, short interpregnancy interval, and lower socioeconomic status (SES) have all been associated with preterm birth. Racial disparities also exist, which seem to persist when taking into account SES. Large population studies have also found associations between maternal genetics and preterm birth. Gestational duration and actual preterm birth have been noted with genetic variants in the maternal genome. Many of these genes have roles in regulation of the estrogen receptor, uterine development, maternal nutrition, or vascular reactivity. In addition, cell free RNA transcripts in maternal blood may also be of value in predicting preterm birth.

Assessment of Gestational Age

With insufficient prenatal care or discrepancies between birthweight and predicted gestational age at birth, it is often helpful to be able to assess infants at birth for an estimated gestational age. Examination and assessment is needed to distinguish SGA and IUGR infants from preterm infants. Compared with a premature infant of appropriate weight, an infant with IUGR has a reduced birthweight and may appear to have a disproportionately larger head relative to body size; infants in both groups lack subcutaneous fat. Neurologic maturity (nerve conduction velocity) in the absence of asphyxia correlates with gestational age despite reduced fetal weight. Physical signs may be useful in estimating gestational age at birth. The commonly used **Ballard scoring system** is accurate to within 2 wk of actual gestational age (Figs. 117.7 to 117.9).



Physical maturity

	–1	0	1	2	3	4	5
Skin	Sticky, friable, transparent	Gelatinous, red, translucent	Smooth, pink, visible veins	Superficial peeling and/or rash, few veins	Cracking, pale areas, rare veins	Parchment, deep cracking, no vessels	Leathery, cracked, wrinkled
Lanugo	None	Sparse	Abundant	Thinning	Bald areas	Mostly bald	
Plantar surface	Heel-toe 40-50 mm: –1 <40 mm: –2	>50 mm, no crease	Faint red marks	Anterior transverse crease only	Creases on ant. 2/3	Creases over entire sole	
Breast	Impercep-tible	Barely perceptible	Flat areola–no bud	Stripped areola, 1-2 mm bud	Raised areola, 3-4 mm bud	Full areola, 5-10 mm bud	
Eye/ear	Lids fused loosely (–1), tightly (–2)	Lids open, pinna flat, stays folded	Slightly curved pinna; soft; slow recoil	Well-curved pinna, soft but ready recoil	Formed and firm, instant recoil	Thick cartilage, ear stiff	
Genitals, male	Scrotum flat, smooth	Scrotum empty, faint rugae	Testes in upper canal, rare rugae	Testes descending, few rugae	Testes down, good rugae	Testes pendulous, deep rugae	
Genitals, female	Clitoris prominent, labia flat	Prominent clitoris, small labia minora	Prominent clitoris, enlarging minora	Majora and minora equally prominent	Majora large, minora small	Majora cover clitoris and minora

Nursery Care

At birth, the general measures needed to clear the airway, initiate breathing, care for the umbilical cord and eyes, and administer vitamin K are the same for premature infants as for those of normal weight and maturity (see Chapter 121). Additional considerations are the need for (1) thermal control and monitoring of the heart rate and respiration, (2) oxygen therapy, and (3) special attention to the details of fluid requirements and nutrition. Safeguards against infection can never be relaxed. Routine procedures that disturb these infants may result in hypoxia. The need for regular and active participation by the parents in the infant's care in the nursery and the question of prognosis for later growth and development require special consideration.

Thermal Control

Neonatal temperature regulation decreases the risk of morbidity and mortality in ELBW and VLBW infants. Neonates in general, and ELBW and VLBW infants to an even greater extent, are at increased risk of heat loss compared with older children due to an increased body surface/weight ratio, decreased epidermal and dermal skin thickness, minimal subcutaneous fat, and an immature nervous system.

Preterm infants should be kept in a **neutral thermal environment** . This environment is a set of thermal conditions, including air and radiating surface temperatures, relative humidity, and airflow, at which heat production (measured experimentally as oxygen consumption) is minimal and the infant's core temperature is within the normal range. The neutral thermal environment is a function of the size and postnatal age of an infant; larger, older infants require lower environmental temperatures than smaller, younger infants. Incubators or radiant warmers can be used to maintain body temperature. Body heat is conserved through provision of a warm environment and humidity. The optimal environmental temperature for minimal heat loss and oxygen consumption for an unclothed infant is one that maintains the infant's core temperature at 36.5-37.0°C (97.7-98.6°F). The smaller and more immature the infant, the higher is the environmental temperature required. Infant warmth can be maintained by heating the air to a desired temperature or by servo-control. Continuous monitoring of the infant's temperature is required to maintain optimal body temperature. **Kangaroo care** with direct skin-to-skin contact between infant and parent, with a hat and blanket covering the infant, is to be encouraged, without untoward effects on thermoregulation.

Maintaining a relative humidity of 40–60% aids in stabilizing body temperature by reducing heat loss at lower environmental temperatures; by preventing drying and irritation of the lining of respiratory passages, especially during the administration of oxygen and after or during endotracheal intubation; and by thinning viscid secretions and reducing insensible water loss. An infant should be weaned and then removed from the incubator or radiant warmer only when the gradual change to the atmosphere of the nursery does not result in a significant change in the infant's temperature, color, activity, or vital signs.

Oxygen Administration

Administering oxygen to reduce the risk of injury from hypoxia and circulatory insufficiency (risk of cerebral palsy, death) must be balanced against the risk of hyperoxia to the eyes (**retinopathy of prematurity, ROP**) and oxygen injury to the lungs (**bronchopulmonary dysplasia, BPD**). For ELBW infants at birth, guidelines should be followed to determine need for oxygen during resuscitation to maintain goal O_2 saturation limits (see Chapter 121).

After the initial resuscitation period, ideal target O_2 saturation limits for ELBW infants should be within the range of 90–95% for most infants.

Nutrition for the High-Risk Infant

Extreme prematurity must be considered a nutritional emergency. In the absence of early parenteral and enteral nutritional support, deficits in protein and energy will quickly accrue, placing the infant at risk for poor growth and neurodevelopmental outcomes. The goals of early nutritional support for extremely premature infants include approximating the rate and composition of growth for a normal fetus at the same postmenstrual age. Achieving this goal requires an understanding of the intrauterine growth rate to be targeted as well as the unique nutrient requirements of premature infants. Strategies to prevent growth faltering include a combined approach of early parenteral and enteral nutrition, fortification of human milk, and the use of standardized feeding guidelines. In addition, careful monitoring of not only weight gain but also length and head circumference using appropriate intrauterine growth curves, as well as consultation with an experienced neonatal dietitian, is important to achieve optimal growth outcomes.

Early Parenteral Nutrition

In the absence of intravenous amino acids, extremely premature infants lose 1-2% of body protein stores per day. IV amino acids and dextrose should be started immediately after birth. Many units use a *starter* or *stock* solution of amino acids and dextrose to accomplish this goal in infants weighing <1,500 g. A minimum of 2 g/kg of amino acids should be given in the 1st 24 hr after birth, with the goal of supplying at least 3.5 g/kg within 24-48 hr after birth. To meet total energy requirements, IV lipids will also be needed.

Benefits of Human Milk

Maternal milk is the preferred source of enteral nutrition for premature infants and is associated with decreased in-hospital morbidity, including lower rates of **necrotizing enterocolitis (NEC)** , late-onset sepsis, BPD, and severe ROP. Maternal milk feeding is also associated with superior neurodevelopmental outcomes at 18 and 30 mo corrected age compared to infants fed premature formula. Donor human milk is increasingly being used when maternal milk is not available, but is typically lower in protein and energy content than preterm maternal milk and may result in suboptimal growth unless adequately fortified. Although donor human milk has been associated with a reduction in NEC, the impact of donor human milk on neurodevelopmental outcomes remains unclear.

Enteral Nutrition

Early enteral feedings are recommended in ELBW and VLBW infants, typically beginning between 6 and 48 hr with some period of trophic/minimal enteral feeding volume. Feedings are typically advanced slowly (15-30 mL/kg/day) with a target goal of delivering approximately 110-135 kcal/kg/day and 3.5-4.5 g protein/kg/day. To accomplish these goals, human milk must be fortified, or a premature formula can be given.

Standardized Feeding Guidelines

Standardized feeding guidelines should be developed incorporating evidence-based strategies for the provision of parenteral and enteral nutrition in ELBW and VLBW infants, including a plan to manage feeding intolerance. Regardless of the specific protocol, having a feeding guideline leads to improved outcomes (e.g., time to regain birthweight, time to reach full enteral nutrition), decreased rates of late-onset sepsis and NEC, improved growth at 36 wk postmenstrual age, and reduced length of hospital stay.

Transitioning to Discharge Nutrition

The earlier an infant is born before expected, the greater the likelihood that not all nutritional deficits will be resolved before hospital discharge. Regardless of weight gain during the initial hospital stay, there is strong evidence for improved bone mineralization with the use of higher concentrations of calcium and phosphorus after discharge. Fortified human milk or preterm formula with higher protein, minerals, and trace elements is often recommended after discharge. An individualized approach to postdischarge nutrition should be developed to transition from the NICU.

Prevention of Infection

Extremely preterm infants have an increased susceptibility to infection, and thus meticulous attention to infection control is required. Prevention strategies include strict compliance with handwashing and universal precautions, minimizing the risk of catheter contamination and duration, meticulous skin care, encouraging early appropriate advancement of enteral feeding, education and feedback to staff, and surveillance of nosocomial infection rates in the nursery. Although no one with an active infection should be permitted in the nursery, the risks of infection must be balanced against the disadvantages of limiting the infant's contact with the family. Early and frequent participation by parents in the nursery care of their infant does not increase the risk of infection when preventive precautions are maintained.

Preventing transmission of infection from infant to infant is difficult because often neither term nor premature newborn infants have clear clinical evidence of an infection early in its course. When epidemics occur within a nursery, cohort nursing and isolation rooms should be used. **Hand hygiene** is of upmost importance. Because premature infants have immature immune function, some will develop nosocomial infection even when all precautions are followed.

Routine **immunizations** should be given on the regular schedule based on chronological age at standard doses.

Immaturity of Drug Metabolism

Great care must be taken when prescribing and dosing medications for premature infants (Table 117.4). Renal clearance of almost all substances excreted in the urine is diminished in newborn infants, and to even a greater extent in premature infants. The glomerular filtration rate rises with increasing gestational age; therefore, drug dosing recommendations vary with age. For drugs primarily excreted by the kidneys, longer intervals between dosages are often needed with increasing degree of prematurity. Drugs that are detoxified in the liver or require chemical conjugation before renal excretion should also be given with caution and in doses smaller than usual.

Table 117.4

Potential Adverse Reactions to Drugs Administered to Premature Infants

DRUG	REACTION(S)
Oxygen	Retinopathy of prematurity, bronchopulmonary dysplasia
Sulfisoxazole	Kernicterus
Chloramphenicol	Gray baby syndrome—shock, bone marrow suppression
Vitamin K analogs	Jaundice
Novobiocin	Jaundice
Hexachlorophene	Encephalopathy
Benzyl alcohol	Acidosis, collapse, intraventricular bleeding
Intravenous vitamin E	Ascites, shock
Phenolic detergents	Jaundice
$NaHCO_3$	Intraventricular hemorrhage
Amphotericin	Anuric renal failure, hypokalemia, hypomagnesemia
Reserpine	Nasal stuffiness
Indomethacin	Oliguria, hyponatremia, intestinal perforation
Cisapride	Prolonged QTc interval
Tetracycline	Enamel hypoplasia
Tolazoline	Hypotension, gastrointestinal bleeding
Calcium salts	Subcutaneous necrosis
Aminoglycosides	Deafness, renal toxicity
Enteric gentamicin	Resistant bacteria
Prostaglandins	Seizures, diarrhea, apnea, hyperostosis, pyloric stenosis
Phenobarbital	Altered state, drowsiness
Morphine	Hypotension, urine retention, withdrawal
Pancuronium	Edema, hypovolemia, hypotension, tachycardia, vecuronium contractions, prolonged hypotonia
Iodine antiseptics	Hypothyroidism, goiter
Fentanyl	Seizures, chest wall rigidity, withdrawal
Dexamethasone	Gastrointestinal bleeding, hypertension, infection, hyperglycemia, cardiomyopathy, reduced growth
Furosemide	Deafness, hyponatremia, hypokalemia, hypochloremia, nephrocalcinosis, biliary stones

Heparin (*not* low-dose prophylactic use)	Bleeding, intraventricular hemorrhage, thrombocytopenia
Erythromycin	Pyloric stenosis

Many drugs apparently safe for adults on the basis of toxicity studies may be harmful to newborns, especially premature infants. Oxygen and a number of drugs have proved toxic to premature infants in amounts not harmful to term infants. Thus, administering any drug, particularly in high doses, that has not undergone pharmacologic testing in premature infants should be undertaken carefully after risks have been weighed against benefits.

Morbidity and Mortality

Rates of neonatal morbidity and mortality are high in extremely preterm infants, and risks increase with decreasing gestational age and lower birthweight (Table 117.5). Data on extremely preterm infants born between 2003 and 2007 found that 42% of VLBW infants developed BPD, 12% developed ROP requiring treatment, 11% NEC, 36% late-onset sepsis, 16% grade III or IV **intraventricular hemorrhage (IVH)** , and 3% **periventricular leukomalacia (PVL)** . Morality increased with lower gestational age, with a 94% mortality in infants born at 22 wk and 8% mortality at 28 wk. As a whole, the group of extremely preterm infants had a 28% mortality rate, with 37% surviving without a significant neonatal morbidity.

Table 117.5

Neonatal Morbidities Associated With Prematurity

RESPIRATORY
Respiratory distress syndrome (hyaline membrane disease)
Bronchopulmonary dysplasia*
Pneumothorax, pneumomediastinum; interstitial emphysema
Congenital pneumonia
Apnea
CARDIOVASCULAR
Patent ductus arteriosus
Hypotension
Bradycardia (with apnea)
HEMATOLOGIC
Anemia (early or late onset)
GASTROINTESTINAL
Poor gastrointestinal function—poor motility

Renal glycosuria
Edema

OTHER

Infections* (congenital, perinatal, nosocomial: bacterial, viral, fungal, protozoal)

* Major neonatal morbidities.

Another study found that morbidity and mortality among VLBW infants decreased between 2000 and 2009. This study was limited to live-born infants with birthweight of 500-1500 g. For infants born in 2009, this study found a 12.4% mortality rate; 28% of infants developed BPD, 7% severe ROP, 5% NEC, 15% late-onset sepsis, 6% grade III or IV IVH, and 3% PVL; 51% survived without significant neonatal morbidity.

Outcomes may be slightly improving with time; survival among infants born 22-24 wk gestation increased from 30% in 2000–2003 to 36% in 2008–2011. The percentage surviving without neurodevelopmental impairment increased from 16% to 20% over this same period. However, extreme prematurity is still associated with significant risk of both mortality and major neonatal morbidities. For infants who survive to discharge, prematurity, as well as neonatal morbidities, put them at increased risk for developmental delays and impairment as they age (see Chapter 117.5).

Moderate and Late Preterm Infants

Jennifer M. Brady, Brenda B. Poindexter

Keywords

late preterm
moderate preterm

WHO defines **moderate to late preterm** birth as infants born between 32 and $36\frac{6}{7}$ wk postmenstrual age (PMA). The American College of Obstetricians and Gynecologists (ACOG) further defines **late preterm** infants as those born between 34 and $36\frac{6}{7}$ wk PMA. Therefore, most define **moderate preterm** infants as those born between 32 and $33\frac{6}{7}$ wk PMA.

Moderate Preterm Infant

Moderate preterm infants are still at risk for most postnatal morbidities, although to a lesser extent than very preterm infants are at risk. These morbidities include but are not limited to poor feeding, weight loss, respiratory distress syndrome, risk of NEC, and difficulty with thermoregulation. Moderate preterm infants with birthweight >1,500 g and a fairly unremarkable NICU course are thought to be at fairly minimal risk for IVH and do not routinely need a head ultrasound. Little research has examined moderate preterm infants as an isolated group; more often these infants are grouped with very preterm infants when assessing complications and outcomes. A cohort of approximately 7,000 infants born between 29 and 33 wk gestational age were found in a recent study to have a mean hospital stay of 33.3 days. Compared with term counterparts, these infants had an increased incidence of many morbidities, including BPD, early- and late-onset sepsis, NEC, and PVL.

Late Preterm Infant

Late preterm infants account for approximately 8–9% of all births and almost three fourths of all preterm births in the United States. Historically, late preterm infants were referred to as *near-term infants*, and the approach to their care was similar to that of term infants. It has been increasingly recognized that late preterm infants have significantly increased morbidity, as well as mortality, compared with their term counterparts. There is an increased incidence of congenital anomalies in preterm infants, but even when these infants are excluded, late preterm infants continue to have significantly more morbidities. Immediately after birth, late preterm infants have an increased risk of requiring resuscitation, as well as increased incidence of hypoglycemia, respiratory distress, apnea, feeding difficulties, and jaundice. They also have a higher rehospitalization rate compared to their term peers.

Antenatal corticosteroids were traditionally only recommended for pregnant women between 24 and 34 wk gestation at risk of preterm delivery within the next 7 days, to reduce the incidence of death and respiratory distress syndrome. A randomized controlled trial of women at $34\text{–}36\frac{6}{7}$ wk gestation at risk of preterm labor found a decreased rate of respiratory complications in the newborns whose mothers received antenatal corticosteroids. An increased rate of neonatal hypoglycemia was seen in the steroid group as well, but no other significant differences were found. Based on these findings, ACOG recommends a single course of antenatal corticosteroids for pregnant women between 34 and $36\frac{6}{7}$ wk gestation at risk for preterm birth within 7 days, who have not received a previous course of antenatal corticosteroids.

Between 34 and $36\frac{6}{7}$ wk gestation is regarded as a critical period for growth and development. In the past, elective deliveries without medical indications often occurred as early as 35 wk. *ACOG recommends elective delivery without medical indications only after 39 wk gestation in well-dated pregnancies.* Some studies suggest a higher risk of lower school readiness at kindergarten and increased risk of academic difficulties in childhood when comparing late preterm infants with term peers.

Term and Postterm Infants

Jennifer M. Brady, Brenda B. Poindexter

Keywords

intrauterine growth restriction
IUGR
large for gestational age
LGA
postterm infant
SGA
small for gestational age

ACOG further divides term infants into subgroups: **early term** ($37-38\frac{6}{7}$ wk), **full term** ($39-40\frac{6}{7}$ wk), and **late term** ($41-41\frac{6}{7}$ wk). Many risk factors for term infants put them at higher risk for complications, such as meconium aspiration syndrome (see Chapter 122.8), hemolytic disease of the newborn (Chapter 124.2), infant of a diabetic mother (Chapter 127.1), and neonatal abstinence syndrome (Chapter 126.1). Both small for gestational age (SGA) and large for gestational age (LGA) are associated with increased morbidities.

Small for Gestational Age and IUGR

There is an important distinction between the terms **small for gestational age (SGA)** and **intrauterine growth restriction (IUGR)** . SGA is based on physical evaluation of an infant at birth, usually by a pediatrician or neonatologist. If the infant's weight is <10th percentile, the infant is SGA. The diagnosis of SGA does not differentiate between normal biologic growth potential and a pathologic or growth-restricted state in utero. In contrast, IUGR is a prenatal diagnosis to describe a fetus who fails to reach in utero growth potential, often diagnosed by the obstetrician. Therefore, not all infants with IUGR are SGA, and similarly, not all infants who are SGA have IUGR.

Although it is important to understand the difference between SGA and IUGR, due to difficulty standardizing a classification of IUGR, many studies evaluate postnatal outcomes based on a diagnosis of either SGA or IUGR.

IUGR is associated with medical conditions that interfere with the circulation and efficiency of the placenta, with the development or growth of the fetus, or with the general health and nutrition of the mother (Table 117.6). Many factors are common to both prematurely born and LBW infants with IUGR. IUGR is associated with decreased insulin production or insulin-like growth factor (IGF) action at the receptor level. Infants with IGF-1 receptor defects, pancreatic hypoplasia, or transient neonatal diabetes have IUGR. Genetic mutations affecting the glucose-sensing mechanisms of the pancreatic islet cells result in decreased insulin release (loss of function of the glucose-sensing glucokinase gene) and give rise to IUGR.

Table 117.6

Factors Often Associated With Intrauterine Growth Restriction

FETAL
Chromosomal disorders
Chronic fetal infections (cytomegalic inclusion disease, congenital rubella, syphilis)
Congenital anomalies—syndrome complexes
Irradiation
Multiple gestation
Pancreatic hypoplasia
Insulin deficiency (production or action of insulin)
Insulin-like growth factor type I deficiency
PLACENTAL
Decreased placental weight, cellularity, or both
Decrease in surface area
Villous placentitis (bacterial, viral, parasitic)
Infarction
Tumor (chorioangioma, hydatidiform mole)
Placental separation
Twin transfusion syndrome
MATERNAL/PATERNAL
Toxemia
Hypertension or renal disease, or both
Hypoxemia (high altitude, cyanotic cardiac or pulmonary disease)
Malnutrition (micronutrient or macronutrient deficiencies)
Chronic illness
Sickle cell anemia
Drugs (narcotics, alcohol, cigarettes, cocaine, antimetabolites)

IGF2 mutation (paternal)

IUGR may be a normal fetal response to nutritional or oxygen deprivation; therefore the issue is not the IUGR but rather the ongoing risk of fetal malnutrition or hypoxia. IUGR is often classified as *reduced growth* that is *symmetric* (head circumference, length, and weight equally affected) or *asymmetric* (with relative sparing of head growth). **Symmetric IUGR** often has an earlier onset in the first trimester of pregnancy and is associated with diseases that seriously affect fetal cell number, such as conditions with chromosomal, genetic, malformation, teratogenic, infectious, or severe maternal hypertensive etiologies. It is important to assess gestational age carefully in infants suspected to have symmetric IUGR because incorrect overestimation of gestational age may lead to the diagnosis of symmetric IUGR. **Asymmetric IUGR** is often of late onset in the 2nd half of pregnancy, demonstrates preservation of Doppler waveform velocity to the carotid vessels, and is associated with poor maternal nutrition or with late onset or exacerbation of maternal vascular disease (preeclampsia, chronic hypertension).

Table 117.7 lists common problems of infants with IUGR. In addition, in both preterm and term infants, SGA has been shown to be associated with an increased risk of neurodevelopmental impairment.

Table 117.7

Problems of Infants Small for Gestational Age or With Intrauterine Growth Restriction*

PROBLEM	PATHOGENESIS
Intrauterine fetal demise	Hypoxia, acidosis, infection, lethal anomaly
Perinatal asphyxia	↓ Uteroplacental perfusion during labor ± chronic fetal hypoxia-acidosis; meconium aspiration syndrome
Hypoglycemia	↓ Tissue glycogen stores, ↓ gluconeogenesis, hyperinsulinism, ↑ glucose needs of hypoxia, hypothermia, large brain
Polycythemia-hyperviscosity	Fetal hypoxia with ↑ erythropoietin production
Reduced oxygen consumption/hypothermia	Hypoxia, hypoglycemia, starvation effect, poor subcutaneous fat stores
Dysmorphology	Syndrome anomalads, chromosomal-genetic disorders, oligohydramnios-induced deformation, TORCH †

[*] Other problems include pulmonary hemorrhage and those common to the gestational age–related risks of prematurity if born at <37 wk.

[†] Toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex infection.

↓, Decreased; ↑, increased.

Large-for-Gestational-Age Infants

Infants with birthweight >90th percentile for gestational age are called **large for**

gestational age (LGA) . Neonatal mortality rates decrease with increasing birthweight until approximately 4,000 g, after which they increase. These oversized infants are usually born at term, but preterm infants with weights high for gestational age also have a significantly higher mortality than infants of the same size born at term; maternal diabetes and obesity are predisposing factors. Some infants are constitutionally large because of large parental size. LGA infants, regardless of their gestational age, have a higher incidence of birth injuries, such as cervical and brachial plexus injuries, phrenic nerve damage with paralysis of the diaphragm, fractured clavicles, cephalohematomas, subdural hematomas, and ecchymoses of the head and face. LGA infants are also at increased risk for hypoglycemia and polycythemia.

The incidence of congenital anomalies, particularly congenital heart disease, is also higher in LGA infants than in term infants of normal weight.

Postterm Infants

Postterm infants are those born after 42 completed wk of gestation, as calculated from the mother's LMP. Historically, approximately 12% of pregnancies resulted in delivery after 42 wk. However, with current evidence suggesting that both morbidity and mortality increase significantly after 42 wk gestation, obstetric interventions to induce labor often occur before 42 wk, resulting in a decreasing rate of postterm births. The cause of postterm birth or postmaturity is unknown. Postterm infants often have normal length and head circumference but may have decreased weight if there is placental insufficiency. Infants born postterm in association with presumed placental insufficiency may have various physical signs. Desquamation, long nails, abundant hair, pale skin, alert faces, and loose skin, especially around the thighs and buttocks, give them the appearance of having recently lost weight; meconium-stained nails, skin, vernix, umbilical cord, and placental membranes may also be noted. Common complications of postmaturity include perinatal depression, meconium aspiration syndrome, persistent pulmonary hypertension, hypoglycemia, hypocalcemia, and polycythemia.

Infants born at ≥42 wk gestational age experience approximately 3 times the mortality of infants born at term. Mortality has been greatly reduced through improved obstetric management. Data suggest that elective delivery during the 39th wk of gestation for both nulliparous and multiparous women is associated with decreased maternal and neonatal complications compared with those who were expectantly managed.

Careful obstetric monitoring, including nonstress testing (NST), biophysical profile (BPP), or Doppler velocimetry, usually provides a rational basis for choosing 1 of 3 courses: nonintervention, induction of labor, or cesarean delivery. Induction of labor or cesarean birth may be indicated in older primigravidas >2-wk beyond term, particularly if evidence of fetal distress is present. Medical problems in the newborn are treated if they arise.

Follow-Up of High-Risk Infants After Discharge

Jennifer M. Brady, Brenda B. Poindexter

Keywords

corrected age
cerebral palsy
developmental delays

early intervention
Individuals with Disabilities Act
neonatal follow-up program

Discharge From the Hospital

Numerous criteria need to be met before a high-risk infant is ready for discharge from the hospital (Table 117.8). Before discharge, infants should be taking most or all nutrition by nipple, either bottle or breast. Some medically fragile infants may be discharged home while receiving gavage feedings after the parents have received appropriate training and education. Growth should be occurring at steady increments, with a goal weight gain of approximately 30 g/day. Temperature should be stable and normal in an open crib. Infants should have had no recent episodes of apnea or bradycardia requiring intervention for at least 5-7 days prior to discharge. Stable infants recovering from BPD may be discharged on a regimen of home oxygen given by nasal cannula as long as careful follow-up is arranged with home pulse oximetry monitoring and outpatient visits. All infants with birthweight <1,500 g or gestational age <30 wk at birth should undergo an eye examination to screen for ROP. If born preterm, hemoglobin or hematocrit should be determined to evaluate for possible anemia of prematurity. Every infant should have a hearing test before discharge. Routine vaccinations should be given based on chronological age before discharge. In addition, palivizumab (Synagis) should be given to eligible infants during **respiratory syncytial virus (RSV)** season immediately before discharge for prophylaxis against RSV, with continued monthly doses arranged as an outpatient as appropriate.

Table 117.8

Readiness for Discharge of High-Risk Infants Criteria

- Resolution of acute life-threatening illnesses
- Ongoing follow-up for chronic but stable problems:
    - Bronchopulmonary dysplasia
    - Intraventricular hemorrhage
    - Necrotizing enterocolitis after surgery or recovery
    - Ventricular septal defect, other cardiac lesions
    - Anemia
    - Retinopathy of prematurity
    - Hearing problems

  - Apnea
  - Cholestasis
- Stable temperature regulation
- Gain of weight with enteral feedings:
  - Breastfeeding
  - Bottle feeding
  - Gastric tube feeding
- Free of significant apnea
- Appropriate immunizations and planning for respiratory syncytial virus prophylaxis if indicated
- Hearing screenings
- Ophthalmologic examination if <30 wk of gestation or <1,500 g at birth
- Parental knowledge, skill, and confidence documented in:
  - Administration of medications (diuretics, methylxanthines, aerosols, etc.)
  - Use of oxygen, apnea monitors, oximeters
- Nutritional support:
  - Timing
  - Volume
  - Mixing concentrated formulas
- Recognition of illness and deterioration
- Basic cardiopulmonary resuscitation
- Infant safety
- Scheduling of referrals:
  - Primary care provider
  - Neonatal follow-up clinic
  - Occupational therapy/physical therapy
- Imaging (head ultrasound)
- Assessment of and solution to social risks

Data from American Academy of Pediatrics, American College of Obstetricians: *Guidelines for perinatal care,* ed 7, Elk Grove Village, IL, 2013, American Academy of Pediatrics.

If all major medical problems have resolved and the home setting is adequate, premature infants may then be discharged when their weight approaches 1,800-2,000 g, they are >34-35 wk PMA, and all the above criteria are met. Parental education, close follow-up, and healthcare provider accessibility are all essential for early discharge protocols. Ideally, the primary caregivers for the infant have a chance to provide infant care in the hospital with nursing supervision and help before discharge home. All high-risk infants should follow-up with their primary care provider within a few days of discharge.

Postdischarge Follow-Up

Medical Follow-Up

Even after discharge from the hospital, high-risk infants need very close medical follow-up. They continued to be at increased risk for poor weight gain and failure to thrive. In the setting of viral illness, premature infants are at increased risk for significant respiratory distress. Infants who are sent home on oxygen need very close medical follow-up with frequent visits and assessments, often with pulmonology. Table 117.9 lists common sequelae of prematurity.

Table 117.9

Sequelae of Prematurity

IMMEDIATE	LATE
Hypoxia, ischemia	Intellectual disability, spastic diplegia, microcephaly, seizures, poor school performance
Intraventricular hemorrhage	Intellectual disability, spasticity, seizures, post hemorrhagic hydrocephalus
Sensorineural injury	Hearing and visual impairment, retinopathy of prematurity, strabismus, myopia
Respiratory failure	Bronchopulmonary dysplasia, pulmonary hypertension, bronchospasm, malnutrition, subglottic stenosis
Necrotizing enterocolitis	Short-bowel syndrome, malabsorption, malnutrition
Cholestatic liver disease	Cirrhosis, hepatic failure, malnutrition
Nutrient deficiency	Osteopenia, fractures, anemia, growth failure
Social stress	Child abuse or neglect, failure to thrive, divorce
Other sequelae	Sudden infant death syndrome, infections, inguinal hernia, cutaneous scars (chest tube, patent ductus arteriosus ligation, intravenous infiltration), gastroesophageal reflux, hypertension, craniosynostosis, cholelithiasis, nephrocalcinosis, cutaneous hemangiomas

Medically complex infants can go home with a multitude of subspecialty appointments to help manage existing morbidities secondary to prematurity. For example, cardiology for management of a patent ductus arteriosus or pulmonary hypertension, pulmonary for BPD, nephrology for hypertension, ophthalmology for ROP, neurosurgery for hydrocephalus, and neurology for history of seizures. The extensive follow-up requirements can be overwhelming and daunting for families. It is very important that these infants have a primary care provider who serves as their “medical home” to help coordinate and assimilate the care from all these providers for families.

Developmental Follow-Up

It is well known that premature infants are at greater risk for **developmental delays** than their term counterparts; the more preterm, the greater the risk of delay. In addition, certain postnatal morbidities (severe BPD, grade III or IV intraventricular hemorrhage, severe ROP) are associated with significantly increased risk of developmental delays. It is very important that preterm infants are followed and assessed for developmental delay, so that if delays are detected, interventions can be instituted early.

It is recommended that developmental follow-up be available for infants born <32 wk PMA, or at a minimum <28 wk PMA and/or <1 kg birthweight. Developmental follow-up in the United States is most often provided in a **neonatal follow-up program** for the 1st 2-3 yr of life, and in some cases, until school age. Assessments focus on 5 main developmental domains: cognitive development, language development, fine and gross motor skills, social development, and emotional development. Although many assessments exist, the most widely used assessment in the United States is the *Bayley Scales of Infant and Toddler Development, Third Edition.*

It is important to note that for at least the 1st 2 yr of life, a child's **corrected age** should be used in determining if a delay exists. Corrected age is calculated by subtracting the weeks born premature from a child's chronological age. In doing so, a corrected age accounts for a child's prematurity. Some debate surrounds whether corrected age should continue to be used after age 2 yr.

If it is determined that a delay exists, a child should be referred for appropriate therapy to help minimize the delay as the child ages. Federal law under the Individuals with Disabilities Act requires states to provide *early intervention* services to children <3 yr old with developmental delay. States vary greatly in how delay is defined and what services are offered. Early intervention is associated with improved cognitive outcomes in infancy and preschool age, but not lasting into school age. Motor outcomes are improved in infancy for children who receive early intervention, but this has not been shown to be a lasting effect into preschool and school age.

Premature infants, especially those with a history of grade III or IV intraventricular hemorrhage or PVL seen on head imaging, are also at increased risk of motor impairments. **Cerebral palsy** is *nonprogressive* but *permanent* disorder of movement and posture caused by disturbance to the developing immature brain. Historically, cerebral palsy had not been diagnosed until 18-24 mo of age, but current tests such as the **General Movements Assessment** (GMA) and **Hammersmith Infant Neurological Examination** (HINE) are helping to identify children at high risk for cerebral palsy within the 1st few mo to yr of life. This enables these children to access early intervention services and therapy at an earlier age, as well as undergo more frequent surveillance as needed.

Children with a history of prematurity who do not show significant developmental delays in the 1st few yr of life are still at risk of later developing learning disabilities, attention problems, and decreased school achievement. Continued screening by their primary care provider may be needed as these children age.

CHAPTER 118

Transport of the Critically Ill Newborn

Jennifer M. Brady, Brenda B. Poindexter

Regionalized Care of Newborns

The concept of **regionalized care** for neonates was first introduced in the 1976 March of Dimes Report *Toward Improving the Outcome of Pregnancy.* This report and future revisions stress the importance of providing regionalized care for infants in facilities with adequate personnel and equipment for an infant's severity of illness. Ideally, mothers deliver infants at a facility with the appropriate level of expertise and resources to care for the degree of prematurity and illness of the infant. Many studies have shown that very-low-birthweight (VLBW) infants, or infants <1,500 g at birth, have decreased morbidity and mortality when delivered at an appropriate level of care center (**Level III** hospitals). In a meta-analysis, neonatal or predischarge death occurred in 38% of VLBW infants receiving care at a non–Level III hospital and 23% of those receiving care at a Level III hospital. A main objective of *Healthy People 2020* addresses this issue, with a goal of increasing the proportion of VLBW infants born at Level III hospitals or subspecialty perinatal centers to 83.7%. Where this is not possible, the infant should be transported to an appropriate level of care hospital after birth.

Levels of Neonatal Care

Although a formal national definition of levels of neonatal care does not exist, the American Academy of Pediatrics (AAP) and March of Dimes have standardized definitions for levels I, II, III, and IV. One must understand the levels of care available before being able to arrange transport to an appropriate facility.

A **Level I** facility must be able to provide *basic neonatal care* . Appropriate equipment and staff must be available to perform neonatal resuscitation and care for healthy term and late preterm infants. In addition, Level I facilities must have the capacity to work to stabilize ill or preterm infants before transport to a higher level of care. A Level I nursery is the minimum requirement for a hospital providing inpatient maternity care. Providers at Level I facilities usually include pediatricians, family physicians, and nurse practitioners.

In addition to the care provided at a Level I facility, **Level II** nurseries must also be capable of providing care to moderately ill term infants with problems expected to resolve quickly. Level II centers also care for infants born ≥32 wk gestational age and >1,500 g at birth, and therefore must be comfortable with treating conditions common in this population, such as difficulty with oral feeds, apnea of prematurity, respiratory distress requiring continuous positive airway pressure (CPAP), and temperature regulation. These centers must also be capable of stabilizing infants born <32 wk gestation and <1,500 g until transfer to a higher-level facility is feasible, including the ability to intubate and provide mechanical ventilation for a brief duration if necessary. In addition to providers in Level I facilities, Level II facilities also typically have pediatric hospitalists, neonatologists, and neonatal nurse practitioners.

Level III neonatal intensive care units (NICUs) are equipped to care for the extremely preterm and critically ill neonates in addition to those infants cared for at Level I and II units. Level III units must have continuously available personnel and equipment to treat conditions commonly seen in this population, such as respiratory distress syndrome, pulmonary hypertension, and need for total parenteral nutrition. Resources should be available to obtain and interpret urgent imaging needed (e.g., CT, echocardiography). Pediatric subspecialists and pediatric surgeons should be available either on site or through prearranged consultative agreements.

In addition to the care available at Level III NICUs, **Level IV** NICUs are also capable of continuously available pediatric subspecialty consultation and pediatric surgical intervention. Many Level IV sites are located at regional children's hospitals and serve to provide outreach education.

Transport of the Critically Ill Neonate

In the event that a neonate requires a higher level of care after birth, transport must be arranged to a unit with the appropriate level of care available. Additional decisions that need to be made before transport include composition of the transport team, equipment required for transport, and mode of transportation.

The composition of the **transport team** varies depending on personnel available and the needs of the infant being transported. The transport team often comprises at least 2 individuals, whether 2 registered nurses (RNs), an RN and a respiratory therapist, or an RN and a paramedic. In addition, occasionally a neonatologist, neonatology fellow, or neonatal nurse practitioner will accompany the transport team for critically ill neonates. A designated **medical control physician** is available and in communication with the transport team throughout the transport as needed.

Transport staff must be competent in the treatment of common neonatal conditions and complications, as well as neonatal procedures. Many Level IV facilities have specialized teams available for neonatal transport. A Cochrane review found no evidence to support or to refute improved infant morbidity or mortality when transport occurred with a specialized team. Depending on the volume of neonatal transports and composition of the team, staff may have limited exposure to neonatal transports and procedures. **Simulation-based learning** is recommended by the AAP Section on Transport Medicine (SOTM) as a method to help achieve and retain competency in rarely experienced procedures, as well as improve team interactions for transport teams.

The **transport vehicle** should be equipped with appropriate medicines, intravenous (IV) fluids, oxygen tanks, catheters, chest tubes, endotracheal tubes (ETTs), laryngoscopes, bag-valve-mask, and infant warming device. It should be well illuminated and have ample room for emergency procedures and monitoring equipment. Additional needs for the specific transport should be anticipated (e.g., nitric oxide).

Common **modes of transport** include ground transport by ambulance and air transport by helicopter or fixed-wing aircraft. The stability of the infant, travel distance, traffic, and weather must all be taken into account when deciding the most appropriate mode of transportation.

Steps should be taken to **stabilize infants** as able in a timely fashion prior to transport. Securing an airway, providing oxygen, assisting with infant ventilation, providing antimicrobial therapy, maintaining the circulation, providing a warmed environment, checking a glucose level, and placing IV or arterial lines or chest tubes should be initiated, if indicated, before transport. Appropriate placement of lines and ETT should be evaluated before transport.

Risks of transport and transportation **consent** should be reviewed and obtained from parents before transport. Although transport teams attempt to anticipate and prepare for possible complications that could occur during transport, there is an inherent risk of complications, including death, in the event of a decompensation during transport resulting from the limited resources and personnel available. Parents should be made aware of these risks. If the infant's condition allows, efforts should be made to allow parents to see their baby briefly before transport.

Communication with the transport team as well as the receiving facility is paramount throughout the transport process. Available prenatal history, information on the infant's resuscitation and hospital course, lab data, and radiographic images should be sent with the transport team to the receiving hospital to aid in future care.

Reverse transport of an infant back to a lower level of care should be considered when infants are stabilized after transport and no longer require the higher level care available at the receiving hospital. Transport back to the birth hospital aids in appropriate utilization of resources, decreases costs of care, and may further promote parent–infant bonding because of proximity to the mother's home.

CHAPTER 119

Clinical Manifestations of Diseases in the Newborn Period

Elizabeth Enlow, James M. Greenberg

A variety of conditions that affect the newborn originate in utero, during birth, or in the immediate postnatal period. These disorders can be caused by prematurity, congenital malformations, disruption of chromosome structure, or acquired diseases and injuries. Recognizing disease in newborn infants requires knowledge of relevant pathophysiology and evaluation of nonspecific clinical signs and symptoms.

Abnormal Movements

Neonatal seizures usually suggest a central nervous system (CNS) disorder, such as hypoxic-ischemic encephalopathy (HIE), intracranial hemorrhage, stroke, cerebral anomaly, subdural effusion, or meningitis (see Chapter 611.7). In the neonate, seizures can also be secondary to hypocalcemia, hypoglycemia, benign familial seizures, or rarely, pyridoxine dependence, hyponatremia, hypernatremia, inborn errors of metabolism, or drug withdrawal.

Seizures in premature infants are often subtle and associated with abnormal eye movement (fluttering, tonic horizontal deviation, sustained eye opening with ocular fixation) or facial movement (chewing, tongue thrusting); the motor component is often that of tonic extension of the limbs, neck, and trunk. Autonomic phenomena include hypertension and tachycardia. Term infants may have focal or multifocal, clonic or myoclonic movements, but they may also have subtler manifestations of seizure activity. **Apnea** may be the 1st manifestation of seizure activity, particularly in a premature infant. Seizures may adversely affect the subsequent neurodevelopmental outcome and may even predispose an infant to seizures outside the neonatal period. Electroencephalographic evidence of seizures can occur without clinical manifestations, particularly in preterm infants. If seizures are suspected, continuous amplitude integrated EEG (aEEG), or more accurately, long-term video EEG monitoring, will improve detection of both subtle and electrographic but clinically silent seizures. Many medications used to treat seizures have important side effects and limited efficacy, but current evidence suggests that the benefits of treating seizures outweigh the risks.

Seizures should be distinguished from the **jitteriness** , defined as *recurrent tremors,* that may be present in normal newborns, in infants of diabetic mothers, in those who experienced birth asphyxia or drug withdrawal, and in polycythemic neonates. An examiner may stop the tremors by holding the infant's extremity; jitteriness often depends on sensory stimuli and occurs when the infant is active, and it is not associated with abnormal eye movements. Tremors are often more rapid with a smaller amplitude than those of tonic-clonic seizures.

After severe birth asphyxia, infants may exhibit **motor automatisms** characterized by recurrent oral-buccal-lingual movements, rotary limb activities (rowing, pedaling, swimming), tonic posturing, or myoclonus. These motor activities are not usually accompanied by time-synchronized EEG discharges, may not signify cortical epileptic activity, respond poorly to anticonvulsant therapy, and are associated with a poor prognosis. Such automatisms may represent cortical depression that produces a brainstem release phenomenon or subcortical seizures.

Failure to move an extremity (**pseudoparalysis**) suggests fracture, dislocation, or nerve injury, often following a traumatic delivery. It is also seen in septic arthritis, osteomyelitis, and other infections that cause pain on movement of the affected part.

Altered Mental Status

Lethargy may be a manifestation of infection, asphyxia, hypoglycemia, hypercapnia, sedation from maternal analgesia or anesthesia, a cerebral defect, or, indeed, almost any severe disease, including an inborn error of metabolism. Shortly after birth, lethargy is most likely caused by maternal medications (opioids, magnesium, general anesthesia) or severe HIE. Lethargy appearing after the 2nd day should suggest infection or an inborn error of metabolism manifesting with hyperammonemia, acidosis, or hypoglycemia. Lethargy with emesis suggests increased intracranial pressure or an inborn error of metabolism.

Irritability may be a sign of discomfort accompanying intraabdominal conditions, meningeal irritation, drug withdrawal, infections, congenital glaucoma, trauma (birth, abuse), or any condition producing pain. It must be distinguished from normal crying behavior associated with hunger or benign environmental stimuli. **Hyperactivity** , especially in a premature infant, may be a sign of hypoxia, pneumothorax, emphysema, hypoglycemia, hypocalcemia, CNS damage, drug withdrawal, neonatal thyrotoxicosis, bronchospasm, esophageal reflux, or discomfort from a cold environment.

Failure to feed is an important sign of the sick newborn infants and should prompt a careful search for infection, a CNS (brain or spine) or peripheral nervous system disorder, inborn error of metabolism, intestinal obstruction, and other abnormal conditions.

Apnea

Periods of apnea, particularly in premature infants, can be attributed to many different underlying causes (see Chapter 122.2). When apnea recurs, or when the intervals are >20 sec or associated with cyanosis or bradycardia, an immediate diagnostic evaluation for the underlying cause is imperative.

Congenital Anomalies

Congenital anomalies are a major cause of stillbirths and in the United States and other developed countries are one of the main causes of neonatal mortality. In addition, congenital anomalies are a major cause of acute illness and long-term morbidity. Anomalies are discussed in general in Chapters 98 and 128 and specifically in the chapters on the various systems of the body. Early recognition of anomalies during fetal life is important to plan for delivery room management and subsequent neonatal care. Some malformations, including congenital heart disease, tracheoesophageal fistula, diaphragmatic hernia, choanal atresia, and intestinal obstruction, require immediate medical/surgical therapy for postnatal survival (Table 119.1). Parents are likely to feel anxious and guilty on learning of the existence of a congenital anomaly and require thoughtful, sensitive counseling.

Table 119.1

Common Life-Threatening Congenital Anomalies

ANOMALY	MANIFESTATIONS
Choanal atresia	Respiratory distress in delivery room; nasogastric tube cannot be passed through nares. Suspect CHARGE (coloboma of eye, heart anomaly, choanal atresia, retardation, genital and ear anomalies) syndrome.
Pierre Robin syndrome, Stickler syndrome	Micrognathia, cleft palate, airway obstruction
Diaphragmatic hernia	Scaphoid abdomen, bowel sounds present in chest, respiratory distress
Tracheoesophageal fistula	Polyhydramnios, aspiration pneumonia, excessive salivation; nasogastric tube cannot be placed in stomach. Suspect VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, radial and renal dysplasia) syndrome.
Intestinal obstruction: volvulus, duodenal atresia, ileal atresia	Polyhydramnios, bile-stained emesis, abdominal distention Suspect trisomy 21, cystic fibrosis, or cocaine use.
Gastroschisis, omphalocele	Polyhydramnios, intestinal obstruction
Renal agenesis, Potter syndrome	Oligohydramnios, anuria, pulmonary hypoplasia, pneumothorax
Neural tube defects: anencephalus, meningomyelocele	Polyhydramnios, elevated α-fetoprotein, decreased fetal activity
Ductus-dependent congenital heart disease	Cyanosis, hypotension, murmur

Cyanosis

Central cyanosis generates a broad differential diagnosis encompassing respiratory, cardiac, CNS, infectious, hematologic, and metabolic etiologies (Table 119.2). Typically, 5 g/dL of deoxyhemoglobin must be present in the blood for central cyanosis to be clinically apparent. If respiratory insufficiency is caused by pulmonary conditions, respirations tend to be rapid with increased work of breathing. If caused by CNS depression, respirations tend to be irregular and weak and are often slow. Cyanosis unaccompanied by obvious signs of respiratory difficulty suggests cyanotic congenital heart disease or methemoglobinemia. Cyanosis resulting from congenital heart disease may, however, be difficult to distinguish clinically from cyanosis caused by respiratory disease. Episodes of cyanosis may also be the initial sign of hypoglycemia, bacteremia, meningitis, shock, or pulmonary hypertension. **Peripheral acrocyanosis** is common in neonates and thought to represent peripheral venous congestion associated with immature control of peripheral vascular tone. It does not usually warrant concern unless poor perfusion is suspected.

Table 119.2

Differential Diagnosis of Cyanosis in the Newborn

CENTRAL OR PERIPHERAL NERVOUS SYSTEM HYPOVENTILATION
Birth asphyxia
Intracranial hypertension, hemorrhage
Oversedation (direct or through maternal route)
Diaphragm palsy
Neuromuscular diseases
Seizures
RESPIRATORY DISEASE
Airway
Choanal atresia/stenosis
Pierre Robin syndrome
Intrinsic airway obstruction (laryngeal/bronchial/tracheal stenosis)
Extrinsic airway obstruction (bronchogenic cyst, duplication cyst, vascular compression)
Lung
Respiratory distress syndrome
Transient tachypnea
Meconium aspiration
Pneumonia (sepsis)
Pneumothorax
Congenital diaphragmatic hernia
Pulmonary hypoplasia
CARDIAC RIGHT-TO-LEFT SHUNT
Abnormal Connections (Pulmonary Blood Flow Normal or Increased)
Transposition of great vessels
Total anomalous pulmonary venous return
Truncus arteriosus
Hypoplastic left heart syndrome
Single ventricle or tricuspid atresia with large ventricular septal defect but without pulmonic stenosis
Obstructed Pulmonary Blood Flow (Pulmonary Blood Flow Decreased)
Pulmonic atresia with intact ventricular septum
Tetralogy of Fallot
Critical pulmonic stenosis with patent foramen ovale or atrial septal defect
Tricuspid atresia
Single ventricle with pulmonic stenosis
Ebstein malformation of tricuspid valve
Persistent fetal circulation (persistent pulmonary hypertension of newborn)
METHEMOGLOBINEMIA
Congenital (hemoglobin M, methemoglobin reductase deficiency)
Acquired (nitrates, nitrites)
Inadequate ambient O_2 or less O_2 delivered than expected (rare)
Disconnection of O_2 supply to nasal cannula, head hood
Connection of air, rather than O_2 , to a mechanical ventilator
SPURIOUS/ARTIFACTUAL
Oximeter artifact (poor contact between probe and skin, poor pulse searching)
Arterial blood gas artifact (contamination with venous blood)
OTHER
Hypoglycemia
Adrenogenital syndrome
Polycythemia
Blood loss

From Smith F: Cyanosis. In Kliegman RM: *Practical strategies in pediatric diagnosis and therapy,* Philadelphia, 1996, Saunders.

Gastrointestinal Disturbances

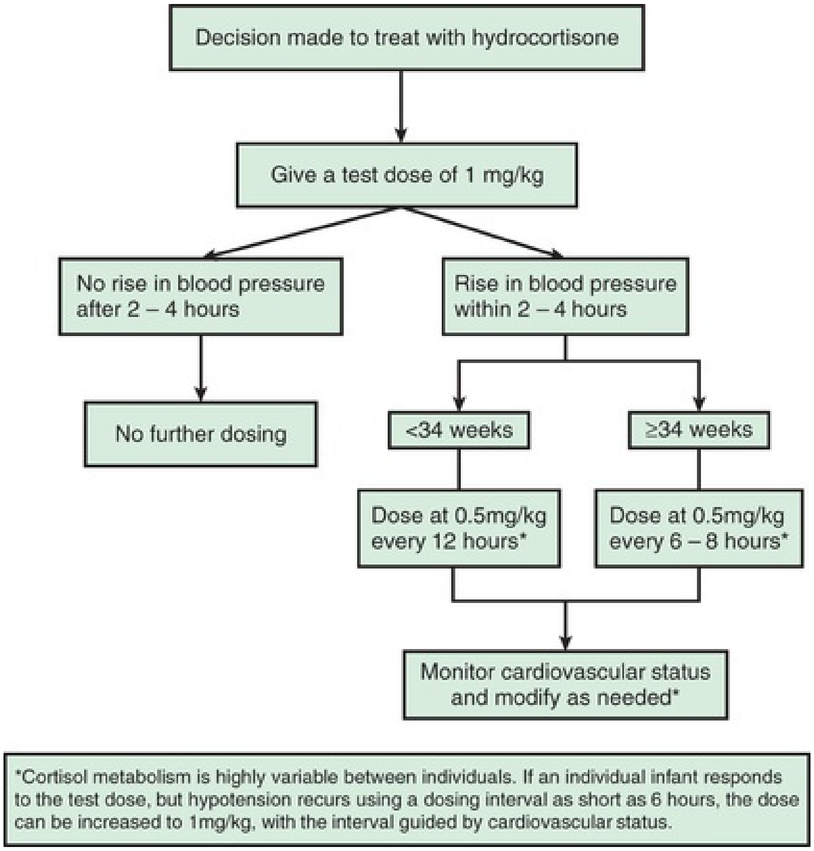
Vomiting during the 1st day of life can suggest obstruction in the upper digestive tract, metabolic disease, or increased intracranial pressure and must be distinguished from benign reflux**. Abdominal distention** with emesis**,** usually a sign of intestinal obstruction or an intraabdominal mass, may also be seen in infants with enteritis, necrotizing enterocolitis (NEC), isolated intestinal perforation, ileus accompanying sepsis, respiratory distress, ascites, or hypokalemia. Imaging studies are indicated when obstruction is suspected; proximal intestinal obstruction often occurs with a normal physical examination, whereas distal obstruction will likely be accompanied by distention. Vomiting may also be a nonspecific symptom of an illness such as septicemia with associated abdominal distention and ileus. It is a common manifestation of overfeeding, inexperienced feeding technique, or normal reflux. Rarely, vomiting is caused by pyloric stenosis, milk allergy, duodenal ulcer, stress ulcer, an inborn error of metabolism (hyperammonemia, metabolic acidosis), or adrenal insufficiency. Vomitus containing dark blood is usually a sign of a serious illness; but the benign possibility of swallowed maternal blood associated with the delivery process should also be considered. Tests for maternal vs fetal hemoglobin can help discriminate between these possibilities. Bilious emesis strongly suggests obstruction below the ampulla of Vater and warrants urgent contrast-enhanced radiography.

Diarrhea may be a symptom of overfeeding (especially high–caloric density formula), acute gastroenteritis, congenital diarrhea syndromes, or malabsorption, or it may be a nonspecific symptom of infection. Diarrhea should be differentiated from the normal loose, seedy, yellow stool seen typically in breastfed infants. Diarrhea may occur in conditions accompanied by compromised circulation of part of the intestinal or genital tract, such as mesenteric thrombosis, NEC, strangulated hernia, intussusception, and torsion of the ovary or testis.

Hypotension

Hypotension in term infants implies hypovolemic shock (hemorrhage, dehydration), a systemic inflammatory response syndrome (bacterial sepsis, intrauterine infection, NEC), cardiac dysfunction (left heart obstructive lesions: hypoplastic left heart syndrome, myocarditis, asphyxia-induced myocardial stunning, anomalous coronary artery), pneumothorax, pneumopericardium, pericardial effusion, or metabolic disorders (hypoglycemia, adrenal insufficiency).

Hypotension is a common problem in sick preterm infants and may also be caused by any of the problems noted in a term infant. Some extremely low gestational age infants do not respond to fluids or inotropic agents but may improve with administration of intravenous hydrocortisone (Fig. 119.1). Sudden onset of hypotension in a very-low-birthweight (VLBW) infant suggests pneumothorax, intraventricular hemorrhage, or subcapsular hepatic hematoma. Strategies used to support blood pressure include volume expansion (normal saline or <5% albumin), vasopressors (dopamine, dobutamine, epinephrine, norepinephrine, vasopressin), or corticosteroids (hydrocortisone) (see Chapter 121).



Decision made to treat with hydrocortisone
Give a test dose of 1 mg/kg
No rise in blood pressure after 2 – 4 hours
Rise in blood pressure within 2 – 4 hours
No further dosing
<34 weeks
≥34 weeks
Dose at 0.5mg/kg every 12 hours*
Dose at 0.5mg/kg every 6 – 8 hours*
Monitor cardiovascular status and modify as needed*

*Cortisol metabolism is highly variable between individuals. If an individual infant responds to the test dose, but hypotension recurs using a dosing interval as short as 6 hours, the dose can be increased to 1mg/kg, with the interval guided by cardiovascular status.

FIG. 119.1 **Suggested treatment algorithm for hydrocortisone dosing in the newborn. (From Watterberg KL: Hydrocortisone dosing for hypotension in newborn infants: less is more, *J Pediatr* 174:23–26, 2016, p 26.e1.)**

Jaundice

Jaundice during the 1st 24 hr of life warrants diagnostic evaluation and should be considered pathologic until proved otherwise. Septicemia and intrauterine or perinatal infections, such as syphilis, cytomegalovirus, and toxoplasmosis, as well as neonatal hemochromatosis, should also be considered, especially in infants with an increase in *direct* bilirubin value. Immediate evaluation includes obtaining total and direct bilirubin, and confirmation as abnormally elevated indicates albumin level, infant blood type and Coombs status, complete blood cell count (CBC), and reticulocyte count. In the case of Coombs-positive hemolysis, strong consideration should be made to giving intravenous immune globulin (IVIG) if there is no response to intensive phototherapy.

Jaundice beyond the 1st 24 hr may be *physiologic* or may be caused by a wide range of conditions, including septicemia, hemolytic anemia, galactosemia, hepatitis, congenital atresia of the bile ducts, inspissated bile syndrome after erythroblastosis fetalis, syphilis, herpes simplex other congenital infections, or other conditions (see Chapter 123.3).

Pain

Pain in neonates may be unrecognized and/or undertreated. The intensive care of neonates may involve several painful procedures, including blood sampling (heelstick, venous or arterial puncture), endotracheal intubation and suctioning, mechanical ventilation, and insertion of chest tubes and intravascular catheters. Pain in neonates results in obvious distress and acute physiologic stress responses, which may have developmental implications for pain in later life. Moreover, knowing that infants may experience pain contributes to parental stress.

Pain and discomfort are potentially avoidable problems during the treatment of sick infants. The most common causes of painful stimuli include circumcision pain and that associated with phlebotomy for metabolic screening tests. **Oral sucrose solutions** are well tolerated by most infants and have proven efficacy for procedural pain. For NICU infants, the most frequently used drugs are intermittent or continuous doses of opioids (morphine, fentanyl) and benzodiazepines (midazolam, lorazepam). Although the long-term effects of opioids and sedatives are not well established, the first concern should be the treatment and/or prevention of acute pain. Continuous opiate infusions should be used with caution. Some minor but painful procedures performed in well neonates can be managed with oral sucrose solutions (Table 119.3).

Table 119.3

Pain in the Neonate: General Considerations

- Pain in newborns is often unrecognized and/or undertreated.
- If a procedure is painful in adults, it should be considered painful in newborns.
- Healthcare institutions should develop and implement patient care policies to assess, prevent, and manage pain in neonates.
- Pharmacologic agents with known pharmacokinetic and pharmacodynamic properties and demonstrated efficacy in neonates should be used. Agents known to compromise cardiorespiratory function should be administered only by persons experienced in neonatal airway management and in settings with the capacity for continuous monitoring.
- Educational programs to increase the skills of healthcare professionals in the assessment and management of stress and pain in neonates should be provided.
- Further research is needed to develop and validate neonatal pain assessment tools that are useful in the clinical

setting; to determine optimal behavioral and pharmacologic interventions; and to study long-term effects of pain and pain management.

Data from American Academy of Pediatrics Committee on Fetus and Newborn, Committee on Drugs, Section on Anesthesiology, Section on Surgery; Canadian Paediatric Society, Fetus and Newborn Committee: Prevention and management of pain and stress in the neonate, *Pediatrics* 105:454–461, 2000; and from Anand KJS; International Evidence-Based Group for Neonatal Pain: Consensus statement for the prevention and management of pain in the newborn, *Arch Pediatr Adolesc Med* 155:173–180, 2001.

119.1

Hyperthermia

Elizabeth Enlow, James M. Greenberg

Serious infection (pneumonia, bacteremia, meningitis, and viral infections, particularly herpes simplex or enteroviruses) may cause **fever** and must be considered, although such infections often occur without provoking a febrile response in newborn infants (see Chapters 201 and 202). Providers should consider evaluation for bacterial infection in infants <28 days old with a rectal temperature ≥38°C (100.5°F), including blood culture, urine culture, and lumbar puncture (LP), although stepwise approaches to identify low-risk patients and limiting LP to a subset of higher-risk infants are gaining favor. Fever immediately after birth may be caused by radiant warmers, maternal fever, or maternal epidural analgesia. Fever may also be caused by elevated environmental temperatures because of weather, overheated nurseries, incubators, or radiant warmers, or excessive clothing. It has also been attributed to dehydration, although *dehydration fever* is a diagnosis of exclusion in newborn infants.

Velasco R, Gomez B, Hernandez-Bou S, et al. Validation of a predictive model for identifying febrile young infants with altered urinalysis at low risk of invasive bacterial infection. *Eur J Clin Microbiol Infect Dis* . 2017;36(2):281–284.

119.2

Hypothermia and Cold Stress

Elizabeth Enlow, James M. Greenberg

Unexplained **hypothermia** may accompany infection or other serious disturbances of the circulation or CNS. A sudden servo-controlled increase in incubator ambient temperature to maintain body temperature is a sign of temperature instability and may be associated with sepsis or any of the conditions already mentioned.

Cold stress can lead to profound decompensation, including apnea, bradycardia, respiratory distress, hypoglycemia, and poor feeding. For this reason, it is paramount for the neonate to maintain normothermia in the delivery room and afterward, especially low-birthweight and premature infants. For VLBW infants, a combination of occlusive plastic wrap, radiant warmers, and thermal mattresses to maintain normothermia can be used to reduce cold stress.

119.3

Edema

Elizabeth Enlow, James M. Greenberg

Generalized edema in a neonate can be caused by hydrops fetalis secondary to several underlying causes (see Chapter 124.2), excessive fluid administration, respiratory disease, sepsis, NEC, and hepatic, renal, or cardiac dysfunction. An infant with suspected hydrops in utero should be delivered at a specialty perinatal center with capacity for neonatal intubation, thoracentesis, paracentesis, and pericardiocentesis in the delivery room.

Desilets V, Audibert F. Investigation and management of non-immune fetal hydrops. *J Obstet Gynaecol Can* . 2013;35(10):923–938.

119.4

Hypocalcemia

Elizabeth Enlow, James M. Greenberg

Hypocalcemia in a neonate can manifest as irritability, jitteriness, clonus, or seizures. Electrocardiography can show a prolonged QT interval. The cause may simply represent an exaggerated physiologic decrease in serum calcium levels within the 1st 24 hr of life or pathologic conditions such as genetic disorders (22q deletions), prematurity, growth restriction, perinatal hypoxia, hypomagnesemia, or maternal diabetes. Hypocalcemia is more common in term infants receiving formula than in those exclusively receiving breast milk. Most infants remain asymptomatic and can be managed conservatively with early nutrition and close monitoring, whereas symptomatic neonates should receive IV or oral calcium replacement.

119.5

Hypermagnesemia

Elizabeth Enlow, James M. Greenberg

Hypermagnesemia is most often caused by maternal administration of magnesium in the perinatal period for treatment of conditions such as preeclampsia and preterm labor, and as prophylaxis to mitigate brain injury associated with preterm birth. Infants are usually present with signs at birth and improve over the next 24-48 hr. Symptoms include respiratory depression, hypotonia, lethargy, and feeding intolerance. No treatment is indicated other than supportive measures.

CHAPTER 120

Nervous System Disorders

Stephanie L. Merhar, Cameron W. Thomas

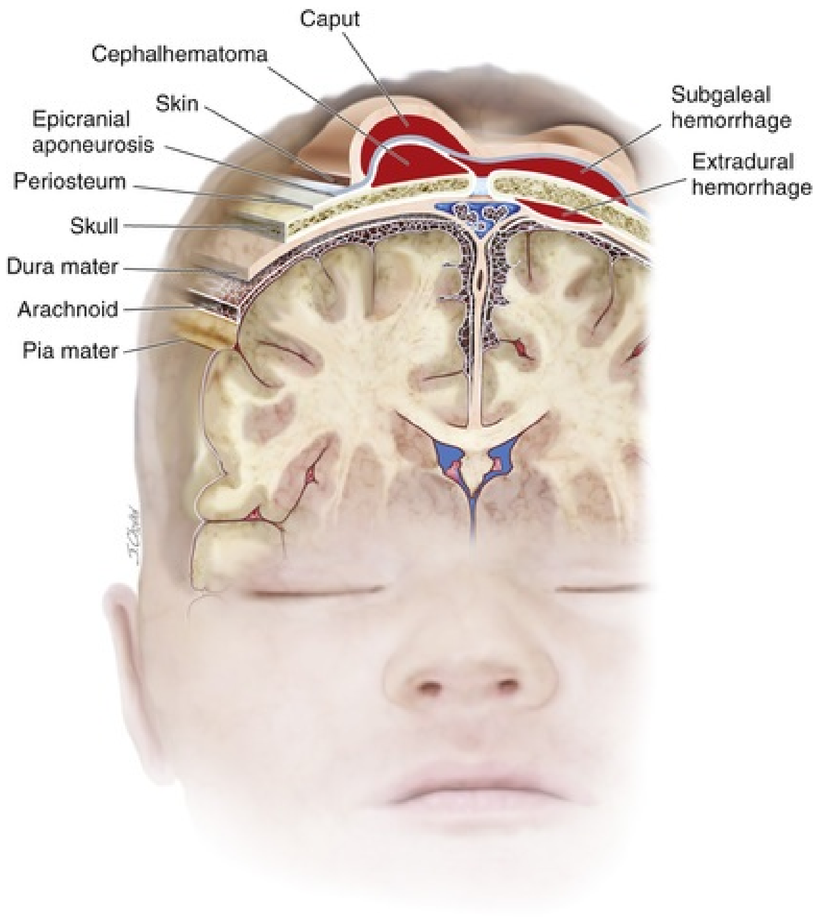
Central nervous system (CNS) disorders are important causes of neonatal mortality and both short-term and long-term morbidity. The CNS can be injured as a result of asphyxia, hemorrhage, trauma, hypoglycemia, or direct cytotoxicity. The etiology of CNS injury is often multifactorial and includes perinatal complications, postnatal hemodynamic instability, and developmental abnormalities that may be genetic and/or environmental. Predisposing factors for brain injury include chronic and acute maternal illness resulting in uteroplacental dysfunction, intrauterine infection, macrosomia/dystocia, malpresentation, prematurity, and intrauterine growth restriction. Acute and often unavoidable emergencies during the delivery process may result in mechanical and hypoxic-ischemic brain injury.

120.1

The Cranium

Stephanie L. Merhar, Cameron W. Thomas

Erythema, abrasions, ecchymoses, and subcutaneous fat necrosis of facial or scalp soft tissues may be noted after a normal delivery or after forceps or vacuum-assisted deliveries. The location depends on the area of contact with the pelvic bones or application of the forceps. Traumatic hemorrhage may involve any layer of the scalp as well as intracranial contents (Fig. 120.1).



Caput
Cephalhematoma
Skin
Epicranial aponeurosis
Periosteum
Skull
Dura mater
Arachnoid

Subgaleal hemorrhage
Extradural hemorrhage

FIG. 120.1 **Sites of extracranial (and extradural) hemorrhages in the newborn. Schematic diagram of important tissue planes from skin to dura. (From Volpe JJ: Injuries of extracranial, cranial, intracranial, spinal cord, and peripheral nervous system structures. In *Volpe's neurology of the newborn,* ed 6, Philadelphia, 2018, Elsevier, Fig 36-1.)**

Caput succedaneum is a diffuse, sometimes ecchymotic, edematous swelling of the soft tissues of the scalp involving the area presenting during vertex delivery. It may extend across the midline and across suture lines. The edema disappears within the 1st few days of life. Molding of the head and overriding of the parietal bones are frequently associated with caput succedaneum and become more evident after the caput has receded; they disappear during the 1st few weeks of life. Rarely, a hemorrhagic caput may result in shock and require blood transfusion. Analogous swelling, discoloration, and distortion of the face are seen in face presentations. No specific treatment is needed, but if extensive ecchymoses are present, hyperbilirubinemia may develop.

Cephalohematoma is a subperiosteal hemorrhage and thus always limited to the *surface* of one cranial bone (Fig. 120.2). Cephalohematomas occur in 1–2% of live births. No discoloration of the overlying scalp occurs, and swelling is not usually visible for several hours after birth because subperiosteal bleeding is a slow process. The lesion becomes a firm, tense mass with a palpable rim localized over one area of the skull. Most cephalohematomas are resorbed within 2 wk to 3 mo, depending on their size. They may begin to calcify by the end of the 2nd wk. A few remain for years as bony protuberances and are detectable on radiographs as widening of the diploic space; cystlike defects may persist for months or years. An underlying skull fracture, usually linear and not depressed, may be associated with 10–25% of cases. A sensation of central depression suggesting but not indicative of an underlying fracture or bony defect is usually encountered on palpation of the organized rim of a cephalohematoma. Cephalohematomas require no treatment, although phototherapy may be necessary to treat hyperbilirubinemia. Infection of the hematoma is a very rare complication.

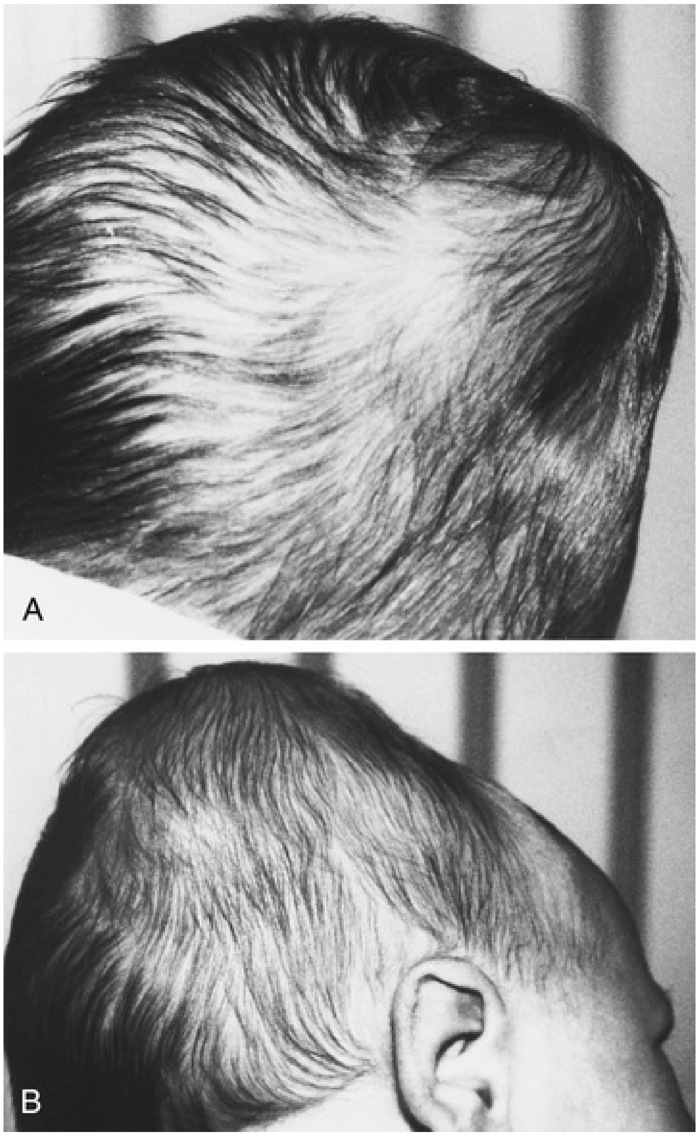

FIG. 120.2 Parietal cephalhematoma. Clinical appearance of 10 day old infant delivered with the aid of mid-forceps. A, Posterior view. B, Right lateral view. Note prominent swelling that extends medially to the sagittal suture, posteriorly to the lambdoid suture, and laterally to the squamosal suture. (From Volpe JJ: Injuries of extracranial, cranial, intracranial, spinal cord, and peripheral nervous system structures. In *Volpe's neurology of the newborn,* ed 6, Philadelphia, 2018, Elsevier, Fig 36-3.)

A **subgaleal hemorrhage** is a collection of blood beneath the aponeurosis that covers the scalp and serves as the insertion for the occipitofrontalis muscle (see Fig. 120.1). Bleeding can be very extensive into this large potential space and may even dissect into subcutaneous tissues of the neck. There is often an association with vacuum-assisted delivery. The mechanism of injury is most likely secondary to rupture of emissary veins connecting the dural sinuses within the skull and the superficial veins of the scalp. Subgaleal hemorrhages are sometimes associated with skull fractures, suture diastasis, and fragmentation of the superior margin of the parietal bone. Extensive subgaleal bleeding is occasionally secondary to a hereditary coagulopathy (**hemophilia**). A subgaleal hemorrhage manifests as a fluctuant mass that straddles cranial sutures or fontanels that increases in size after birth. Some patients have a consumptive coagulopathy from massive blood loss. Patients should be monitored for hypotension, anemia, and hyperbilirubinemia. These lesions typically resolve over 2-3 wk.

Fractures of the skull may be caused by pressure from forceps or the maternal pelvis or by accidental falls after birth. *Linear fractures*, the most common, cause no symptoms and require no treatment. Linear fractures should be followed up to demonstrate healing and to detect the possible complication of a leptomeningeal cyst. *Depressed fractures* indent the calvaria similar to dents in a Ping-Pong ball. They are generally a complication of forceps delivery or fetal compression. Affected infants may be asymptomatic unless they have associated intracranial injury; it is advisable to elevate severe depressions to prevent cortical injury from sustained pressure. Although some may elevate spontaneously, some require treatment. Use of a breast pump or vacuum extractor may obviate the need for neurosurgical intervention. Suspected skull fractures should be evaluated with CT (3D reconstruction may be helpful) to confirm fracture and rule out associated intracranial injury.

Subconjunctival and **retinal hemorrhages** are frequent; petechiae of the skin of the head and neck are also common. All are probably secondary to a sudden increase in intrathoracic pressure during passage of the chest through the birth canal. Parents should be assured that these hemorrhages are temporary and the result of normal events of delivery. The lesions resolve rapidly within the 1st 2 wk of life.

120.2

Traumatic, Epidural, Subdural, and Subarachnoid Hemorrhage

Stephanie L. Merhar, Cameron W. Thomas

Traumatic epidural, subdural, or subarachnoid hemorrhage is especially likely when the fetal head is large in proportion to the size of the mother's pelvic outlet, with prolonged labor, in breech or precipitous deliveries, or as a result of mechanical assistance with delivery. Massive **subdural hemorrhage** , often associated with tears in the tentorium cerebelli or less frequently in the falx cerebri, is rare but is encountered more often in full-term than in premature infants. Patients with massive hemorrhage caused by tears of the tentorium or falx cerebri rapidly deteriorate and may die soon after birth. Most subdural and epidural hemorrhages resolve without intervention. Consultation with a neurosurgeon is recommended. Asymptomatic subdural hemorrhage may be noted within 48 hr of birth after vaginal or cesarean delivery. These are typically small hemorrhages, especially common in the posterior fossa, discovered incidentally in term infants imaged in the neonatal period and usually of no clinical significance. The diagnosis of large subdural hemorrhage may be delayed until the chronic subdural fluid volume expands and produces macrocephaly, frontal bossing, a bulging fontanel, anemia, and sometimes seizures. CT scan and MRI are useful imaging techniques to confirm these diagnoses. Symptomatic subdural hemorrhage in term infants can be treated by a neurosurgical evacuation of the subdural fluid collection by a needle placed through the lateral margin of the anterior fontanel. In addition to birth trauma, **child abuse** must be suspected in all infants with subdural effusion after the immediate neonatal period. Most asymptomatic subdural hemorrhages following labor should resolve by 4 wk of age.

Subarachnoid hemorrhage is often clinically silent in the neonate. Anastomoses between the penetrating leptomeningeal arteries or the bridging veins are the most likely source of the bleeding. Most affected infants have no clinical symptoms, but the subarachnoid hemorrhage may be detected because of an elevated number of red blood cells in a lumbar puncture sample. Some infants experience short, benign seizures, which tend to occur on the 2nd day of life. Rarely, an infant has a catastrophic hemorrhage and dies. There are usually no neurologic abnormalities during the acute episode or on follow-up. Significant neurologic findings should suggest an arteriovenous malformation, which can best be detected on CT or MRI.

120.3

Intracranial-Intraventricular Hemorrhage and Periventricular Leukomalacia

---

Stephanie L. Merhar, Cameron W. Thomas

Etiology

Intracranial hemorrhage in preterm infants usually develops spontaneously. Less frequently, it may be caused by trauma or asphyxia, and rarely, it occurs from a primary hemorrhagic disturbance or congenital cerebrovascular anomaly. Intracranial hemorrhage often involves the ventricles (**intraventricular hemorrhage, IVH**) of premature infants delivered spontaneously without apparent trauma. The IVH in premature infants is usually not present at birth but may develop during the 1st week of life. Primary hemorrhagic disturbances and vascular malformations are rare and usually give rise to subarachnoid or intracerebral hemorrhage. In utero hemorrhage associated with maternal idiopathic or, more often, fetal alloimmune thrombocytopenia may appear as severe cerebral hemorrhage or as a porencephalic cyst after resolution of a fetal cortical hemorrhage. Intracranial bleeding may be associated with disseminated intravascular coagulation, isoimmune thrombocytopenia, and neonatal vitamin K deficiency, especially in infants born to mothers receiving phenobarbital or phenytoin.

Epidemiology

The overall incidence of IVH has decreased over the past decades as a result of improved perinatal care, increased use of antenatal corticosteroids, surfactant to treat respiratory distress syndrome (RDS), and possibly prophylactic indomethacin. It continues to be an important cause of morbidity in preterm infants, as approximately 30% of premature infants <1,500 g have IVH. The risk is inversely related to gestational age and birthweight; 7% of infants weighing 1,001-1,500 g have a severe IVH (grade III or IV), compared to 14% of infants weighing 751-1,000 g and 24% of infants ≤750 g. In 3% of infants <1,000 g, **periventricular leukomalacia (PVL)** develops.

Pathogenesis

The major neuropathologic lesions associated with very-low-birthweight (VLBW) infants are IVH and PVL. IVH in premature infants occurs in the gelatinous subependymal **germinal matrix** . This periventricular area is the site of origin for embryonal neurons and fetal glial cells, which migrate outwardly to the cortex. Immature blood vessels in this highly vascular region of the developing brain combined with poor tissue vascular support predispose premature infants to hemorrhage. The germinal matrix involutes as the infant approaches full-term gestation, and the tissue's vascular integrity improves; therefore IVH is much less common in the term infant. The cerebellum also contains a germinal matrix and is susceptible to hemorrhagic injury. **Periventricular hemorrhagic infarction** , previously known as **grade IV intraventricular hemorrhage** , often develops after a large IVH because of venous congestion. Predisposing factors for IVH include prematurity, RDS, hypoxia-ischemia, exaggerated fluctuations in cerebral blood flow (hypotensive injury, hypervolemia, hypertension), reperfusion injury of damaged vessels, reduced vascular integrity, increased venous pressure (pneumothorax, venous thrombus), or thrombocytopenia.

Understanding of the pathogenesis of PVL is evolving, and it appears to involve both intrauterine and postnatal events. A complex interaction exists between the development of the cerebral vasculature and the regulation of cerebral blood flow (both of which depend on gestational age), disturbances in the oligodendrocyte precursors required for myelination, and maternal/fetal infection and inflammation. Postnatal hypoxia or hypotension, necrotizing enterocolitis (NEC) with its resultant inflammation, and severe neonatal infection may all result in white matter injury. PVL is characterized by focal necrotic lesions in the periventricular white matter and/or more diffuse white matter damage. Destructive focal necrotic lesions resulting from massive cell death are less common in the modern era. Instead, diffuse injury leading to abnormal maturation of neurons and glia is more frequently seen. The risk for PVL increases in infants with severe IVH or ventriculomegaly. Infants with PVL are at higher risk of cerebral palsy because of injury to the corticospinal tracts that descend through the periventricular white matter.

Clinical Manifestations

Most infants with **IVH** , including some with moderate to severe hemorrhages, have no initial clinical signs (**silent** IVH). Some premature infants in whom severe IVH develops may have acute deterioration on the 2nd or 3rd day of life (**catastrophic** presentation). Hypotension, apnea, pallor, stupor or coma, seizures, decreased muscle tone, metabolic acidosis, shock, and decreased hematocrit (or failure of hematocrit to increase after transfusion) may be the first clinical indications. A saltatory progression may evolve over several hours to days and manifest as intermittent or progressive alterations of levels of consciousness, abnormalities of tone and movement, respiratory signs, and eventually other features of the acute catastrophic IVH. Rarely, IVH may manifest at birth or even prenatally; 50% of cases are diagnosed within the 1st day of life, and up to 75% within the 1st 3 days. A small percentage of infants have late hemorrhage, between days 14 and 30. IVH as a primary event is rare after the 1st mo of life.

PVL is usually clinically asymptomatic until the neurologic sequelae of white matter damage become apparent in later infancy as spasticity and/or motor deficits. PVL may be present at birth but usually occurs later, when the echodense phase is seen on ultrasound (3-10 days of life), followed by the typical echolucent/cystic phase (14-20 days).

The severity of hemorrhage is defined by the location and degree of bleeding and ventricular dilation on cranial imaging. In a **grade I** hemorrhage, bleeding is isolated to the subependymal area. In **grade II** hemorrhage, there is bleeding within the ventricle without evidence of ventricular dilation. **Grade III** hemorrhage is IVH with ventricular dilation. In **grade IV** hemorrhage, there is intraventricular and parenchymal hemorrhage (Fig. 120.3). Another grading system describes 3 levels of increasing severity of IVH detected on ultrasound: In **grade I,** bleeding is confined to the germinal matrix–subependymal region or to <10% of the ventricle (approximately 35% of IVH cases); **grade II** is defined as intraventricular bleeding with 10–50% filling of the ventricle (40% of IVH cases); and in **grade III** , >50% of the ventricle is involved, with dilated ventricles (Fig. 120.3). **Ventriculomegaly** is defined as mild (0.5-1 cm dilation), moderate (1.0-1.5 cm dilation), or severe (>1.5 cm dilation).

FIG. 120.3 **Grading of the severity of germinal matrix–intraventricular hemorrhage (IVH): coronal (cor) and parasagittal (sag) ultrasound scans. A, Germinal matrix hemorrhage, grade I. B, IVH (filling <50% of ventricular area), grade II. C, IVH with ventricular dilatation, grade III. D, Large IVH with associated parenchymal echogenicity (hemorrhagic infarct), grade IV. (From Inder TE, Perlman JM, Volpe JJ: Preterm intraventricular hemorrhage/posthemorrhagic hydrocephalus. In *Volpe's neurology of the newborn,* ed 6, Philadelphia, 2018, Elsevier, Fig 24-2.)**

Diagnosis

Intracranial hemorrhage is suspected on the basis of history, clinical manifestations, and knowledge of the birthweight-specific risks for **IVH** . Associated clinical signs of IVH are typically nonspecific or absent; therefore, it is recommended that premature infants <32 wk of gestation be evaluated with routine real-time cranial ultrasonography (US) through the anterior fontanel to screen for IVH. Infants <1,000 g are at highest risk and should undergo cranial US within the 1st 3-7 days of age, when approximately 75% of lesions will be detectable. US is the preferred imaging technique for screening because it is noninvasive, portable, reproducible, and sensitive and specific for detection of IVH. All at-risk infants should undergo follow-up US at 36-40 wk postmenstrual age to evaluate adequately for PVL, as cystic changes related to perinatal injury may not be visible for up to 1 mo. In one study, 29% of low-birthweight (LBW) infants who later experienced cerebral palsy did not have radiographic evidence of PVL until after 28 days of age. US also detects the precystic and cystic symmetric lesions of PVL and the asymmetric intraparenchymal echogenic lesions of cortical hemorrhagic infarction (Fig. 120.4). Cranial US may be useful in monitoring delayed development of cortical atrophy, porencephaly, and the severity, progression, or regression of posthemorrhagic hydrocephalus.

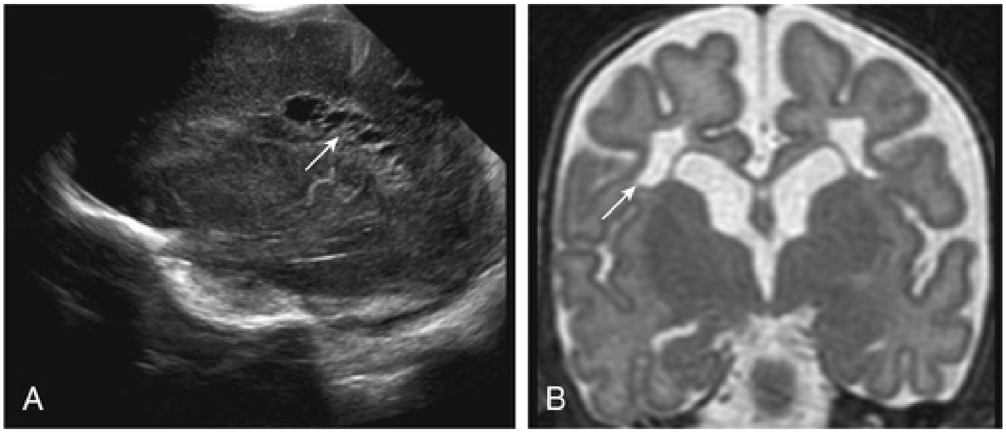

FIG. 120.4 **Severe cystic periventricular leukomalacia. A, Parasagittal ultrasound image showing numerous large cysts superolateral to the lateral ventricle *(arrow)* . B, Coronal T_2 -weighted MR image in which cysts are present superolateral to the lateral ventricles *(arrow)* . (From Neil JJ, Volpe JJ: Encephalopathy of prematurity: clinical-neurological features, diagnosis, imaging, prognosis, therapy. In *Volpe's neurology of the newborn,* ed 6, Philadelphia, 2018, Elsevier, Fig 16-1.)**

Approximately 3–5% of VLBW infants develop **posthemorrhagic hydrocephalus (PHH)** . If the initial US findings are abnormal, additional interval US studies are indicated to monitor for the development of hydrocephalus and potential need for ventriculoperitoneal shunt insertion.

IVH represents only 1 facet of brain injury in the term or preterm infant. MRI is a more sensitive tool for evaluation of white matter abnormalities and cerebellar injury and may be more predictive of adverse long-term outcome.

Prognosis

The degree of **IVH** and presence of **PVL** are strongly linked to survival and neurodevelopmental impairment (Tables 120.1 and 120.2). For infants with birthweight <1,000 g, the incidence of severe neurologic impairment (defined as Bayley Scales of Infant Development II mental developmental index <70, psychomotor development index <70, cerebral palsy, blindness, or deafness) after IVH is highest with grade IV hemorrhage and lower birthweight. PVL, cystic PVL, and progressive hydrocephalus requiring shunt insertion are each independently associated with a poorer prognosis (Table 120.3). Current data suggest that outcomes for infants with grade III/IV intraventricular hemorrhage may be improving, with rates of cerebral palsy and neurodevelopmental impairment closer to 30–40% at age 2 yr.

Table 120.1

Short-Term Outcome of Germinal Matrix–Intraventricular Hemorrhage as a Function of Severity of Hemorrhage and Birthweight[*]

SEVERITY OF HEMORRHAGE	DEATHS IN FIRST 14 DAYS[c]		PVD (SURVIVORS >14 DAYS)	
	<750 g (*n* = 75)	**751-1500 g (*n* = 173)**	**<750 g (*n* = 56)**	**751-1500 g (*n* = 165)**
Grade I	3/24 (12)	0/80 (0)	1/21 (5)	3/80 (4)
Grade II	5/21 (24)	1/44 (2)	1/16 (6)	6/43 (14)
Grade III	6/19 (32)	2/26 (8)	10/13 (77)	18/24 (75)
Grade III and apparent PHI	5/11 (45)	5/23 (22)	5/6 (83)	12/18 (66)

[*] Values are *n* (%). Deaths occurring later in the neonatal period are not shown; the total mortality rates (early and late deaths) are approximately 50–100% greater for each grade of hemorrhage and birthweight than those shown in the table for early deaths alone.

PHI, Periventricular hemorrhagic infarction; PVD, progressive ventricular dilation.

Data from Murphy BP, Inder TE, Rooks V, Taylor GA, et al. Posthemorrhagic ventricular dilatation in the premature infant: natural history and predictors of outcome, *Arch Dis Child Fetal Neonatal Ed* 87:F37–F41, 2002.

Adapted from Inder TE, Perlman JM, Volpe JJ: Preterm intraventricular hemorrhage/posthemorrhagic hydrocephalus. In *Volpe's neurology of the newborn,* ed 6, Philadelphia, 2018, Elsevier (Table 24-15).

Table 120.2

Long-Term Outcome: Neurologic Sequelae in Survivors With Germinal Matrix–Intraventricular Hemorrhage as a Function of Severity of Hemorrhage[*]

SEVERITY OF HEMORRHAGE[b]	INCIDENCE OF DEFINITE NEUROLOGIC SEQUELAE [†] (%)
Grade I	15
Grade II	25
Grade III	50
Grade III and apparent PVI	75

[*] Data are derived from reports published since 2002 and include personal published and unpublished cases. Mean values (to nearest 5%); considerable variability among studies was apparent, especially for the severe lesions.

[†] Definite neurologic sequelae included principally cerebral palsy or mental retardation, or both.

PVI, Periventricular hemorrhagic infarction.

Adapted From Inder TE, Perlman JM, Volpe JJ: Preterm intraventricular hemorrhage/posthemorrhagic hydrocephalus. In *Volpe's neurology of the newborn,* ed 6, Philadelphia, 2018, Elsevier (Table 24-16).

Table 120.3

Ultrasonographic (US) Diagnosis of Periventricular Leukomalacia

US APPEARANCE	TEMPORAL FEATURES	NEUROPATHOLOGIC CORRELATION
Echogenic foci, bilateral, posterior > anterior	1st wk	Necrosis with congestion and/or hemorrhage (size >1 cm)
Echolucent foci (“cysts”)	1-3 wk	Cyst formation secondary to tissue dissolution (size >3 mm)
Ventricular enlargement, often with disappearance of “cysts”	≥2-3 mo	Deficient myelin formation; gliosis, often with collapse of cyst

From Neil JJ, Volpe JJ: Encephalopathy of prematurity: clinical-neurological features, diagnosis, imaging, prognosis, therapy. In *Volpe's neurology of the newborn,* ed 6, Philadelphia, 2018, Elsevier (Table 16-6).

Most infants with IVH and acute ventricular distention do not have **PHH** . Only 10–15% of LBW neonates with IVH develop PHH, which may initially present without clinical signs (enlarging head circumference, lethargy, a bulging fontanel or widely split sutures, apnea, and bradycardia). In infants in whom symptomatic hydrocephalus develops, clinical signs may be delayed 2-4 wk despite progressive ventricular distention and compression and thinning of the cerebral cortex. Many infants with PHH have spontaneous regression; only 3–5% of VLBW infants with PHH ultimately require shunt insertion. Those infants who require shunt insertion for PHH have lower cognitive and psychomotor performance at 18-22 mo.

Prevention

Improved perinatal care is imperative to minimize traumatic brain injury and decrease the risk of preterm delivery. The incidence of traumatic intracranial hemorrhage may be reduced by judicious management of cephalopelvic disproportion and operative (forceps, vacuum) delivery. Fetal or neonatal hemorrhage caused by maternal idiopathic thrombocytopenic purpura or alloimmune thrombocytopenia may be reduced by maternal treatment with corticosteroids, intravenous immune globulin (IVIG), fetal platelet transfusion, or cesarean birth. Meticulous care of the LBW infant's respiratory status and fluid-electrolyte management—avoidance of acidosis, hypocarbia, hypoxia, hypotension, wide fluctuations in neonatal blood pressure or P_{CO_2} (and secondarily fluctuation in cerebral perfusion pressure), and pneumothorax—are important factors that may affect the risk for development of IVH and PVL.

A single course of antenatal corticosteroids is recommended in pregnancies 24-37 wk of gestation that are at risk for preterm delivery. Antenatal steroids decrease the risk of death, grades III and IV intraventricular hemorrhage, and PVL in the neonate. The prophylactic administration of low-dose indomethacin (0.1 mg/kg/day for 3 days) to VLBW preterm infants reduces the incidence of severe IVH.

Treatment

Although no treatment is available for **IVH** that has occurred, it may be associated with other complications that require therapy. Seizures should be treated with anticonvulsant drugs. Anemia and coagulopathy require transfusion with packed red blood cells or fresh-frozen plasma. Shock and acidosis are treated with fluid resuscitation.

Insertion of a **ventriculoperitoneal shunt** is the preferred method to treat progressive and symptomatic **PHH** . Some infants require temporary cerebrospinal fluid diversion before a permanent shunt can be safety inserted. Diuretics and acetazolamide are not effective. Ventricular taps or reservoirs and externalized ventricular drains are potential temporizing interventions, although there is an associated risk of infection and *puncture porencephaly* from injury to the surrounding parenchyma. A **ventriculosubgaleal shunt** inserted from the ventricle into a surgically created subgaleal pocket provides a closed system for constant ventricular decompression without these additional risk factors. Decompression is regulated by the pressure gradient between the ventricle and the subgaleal pocket.

120.4

Hypoxic-Ischemic Encephalopathy

Cameron W. Thomas, Stephanie L. Merhar

Hypoxemia , a decreased arterial concentration of oxygen, frequently results in **hypoxia** , or decreased oxygenation to cells or organs. **Ischemia** refers to blood flow to cells or organs that is inadequate to maintain physiologic function. **Hypoxic-ischemic encephalopathy (HIE)** is a leading cause of neonatal brain injury, morbidity, and mortality globally. In the developed world, incidence is estimated at 1-8 per 1,000 live births, and in the developing world, estimates are as high as 26 per 1,000.

Approximately 20–30% of infants with HIE (depending on the severity) die in the neonatal period, and 33–50% of survivors are left with permanent neurodevelopmental abnormalities (cerebral palsy, decreased IQ, learning/cognitive impairment). The greatest risk of adverse outcome is seen in infants with severe fetal acidosis (pH <6.7) (90% death/impairment) and a base deficit >25 mmol/L (72% mortality). Multiorgan failure and insult can occur (Table 120.4).

Table 120.4

Multiorgan Systemic Effects of Asphyxia

SYSTEM	EFFECTS
Central nervous	Hypoxic-ischemic encephalopathy, infarction, intracranial hemorrhage, seizures, cerebral edema, hypotonia, hypertonia
Cardiovascular	Myocardial ischemia, poor contractility, cardiac stunning, tricuspid insufficiency, hypotension
Pulmonary	Pulmonary hypertension, pulmonary hemorrhage, respiratory distress syndrome
Renal	Acute tubular or cortical necrosis
Adrenal	Adrenal hemorrhage
Gastrointestinal	Perforation, ulceration with hemorrhage, necrosis
Metabolic	Inappropriate secretion of antidiuretic hormone, hyponatremia, hypoglycemia, hypocalcemia, myoglobinuria
Integumentary	Subcutaneous fat necrosis
Hematologic	Disseminated intravascular coagulation

Etiology

Most neonatal encephalopathy and seizure, in the absence of major congenital malformations or metabolic or genetic syndromes, appear to be caused by perinatal events. Brain MRI or autopsy findings in full-term neonates with encephalopathy demonstrate that 80% have acute injuries, <1% have prenatal injuries, and 3% have non–hypoxic-ischemic diagnoses. Fetal hypoxia may be caused by various disorders in the mother, including: (1) inadequate oxygenation of maternal blood from hypoventilation during anesthesia, cyanotic heart disease, respiratory failure, or carbon monoxide poisoning; (2) low maternal blood pressure from acute blood loss, spinal anesthesia, or compression of the vena cava and aorta by the gravid uterus; (3) inadequate relaxation of the uterus to permit placental filling as a result of uterine tetany caused by the administration of excessive oxytocin; (4) premature separation of the placenta; (5) impedance to the circulation of blood through the umbilical cord as a result of compression or knotting of the cord; and (6) placental insufficiency from maternal infections, exposures, diabetes, toxemia or postmaturity.

Placental insufficiency often remains undetected on clinical assessment. Intrauterine growth restriction may develop in chronically hypoxic fetuses without the traditional signs of fetal distress. Doppler umbilical waveform velocimetry (demonstrating increased fetal vascular resistance) and cordocentesis (demonstrating fetal hypoxia and lactic acidosis) identify a chronically hypoxic infant (see Chapter 115). Uterine contractions may further reduce umbilical oxygenation, depressing the fetal cardiovascular system and CNS and resulting in low Apgar scores and respiratory depression at birth.

After birth, hypoxia may be caused by (1) failure of oxygenation as a result of severe forms of cyanotic congenital heart disease or severe pulmonary disease; (2) severe anemia (severe hemorrhage, hemolytic disease); (3) shock severe enough to interfere with the transport of oxygen to vital organs from overwhelming sepsis, massive blood loss, and intracranial or adrenal hemorrhage; or (4) failure to breathe after birth because of in utero CNS injury or drug-induced suppression.

Pathophysiology and Pathology

The topography of cerebral injury typically correlates with areas of decreased cerebral blood flow and areas of relatively higher metabolic demand, although regional vulnerabilities are impacted by gestational age and severity of insult (Table 120.5). After an episode of hypoxia and ischemia, anaerobic metabolism occurs and generates increased amounts of lactate and inorganic phosphates. Excitatory and toxic amino acids, particularly glutamate, accumulate in the damaged tissue. prompting overactivation of *N* -methyl-ᴅ -aspartate (NMDA), amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA), and kainate receptors. This receptor overactivation increases cellular permeability to sodium and calcium ions. Because of inadequate intracellular energy, normal sodium and calcium homeostasis is lost, and intracellular accumulation of these ions results in cytotoxic edema and neuronal death. Intracellular calcium accumulation may also result in apoptotic cell death. Concurrent with the excitotoxic cascade, there is also increased production of damaging free radicals and nitric oxide in these tissues. The initial circulatory response of the fetus is increased shunting through the ductus venosus, ductus arteriosus, and foramen ovale, with transient maintenance of perfusion of the brain, heart, and adrenals in preference to the lungs, liver, kidneys, and intestine. Thus, serum laboratory evidence of injury to these organs may be present in more severe cases.

Table 120.5

Topography of Brain Injury in Term Infants With Hypoxic-Ischemic Encephalopathy and Clinical Correlates

AREA OF INJURY	LOCATION OF INJURY	CLINICAL CORRELATES	LONG-TERM SEQUELAE
Selective neuronal necrosis	Entire neuraxis, deep cortical area, brainstem and pontosubicular	Stupor or coma Seizures Hypotonia Oculomotor abnormalities Suck/swallow abnormalities	Cognitive delay Cerebral palsy Dystonia Seizure disorder Ataxia Bulbar and pseudobulbar palsy
Parasagittal injury	Cortex and subcortical white matter Parasagittal regions, especially posterior	Proximal-limb weakness Upper extremities affected > lower extremities	Spastic quadriparesis Cognitive delay Visual and auditory processing difficulty
Focal ischemic necrosis	Cortex and subcortical white matter Vascular injury (usually middle cerebral artery distribution)	Unilateral findings Seizures common and typically focal	Hemiparesis Seizures Cognitive delays
Periventricular injury	Injury to motor tracts, especially lower extremity	Bilateral and symmetric weakness in lower extremities More common in preterm infants	Spastic diplegia

Adapted from Volpe JJ, editor: *Neurology of the newborn* , ed 4, Philadelphia, 2001, Saunders.

The pathology of hypoxia-ischemia outside the CNS depends on the affected organ and the severity of the injury. Early congestion, fluid leak from increased capillary permeability, and endothelial cell swelling may lead to signs of coagulation necrosis and cell death. Congestion and petechiae are seen in the pericardium, pleura, thymus, heart, adrenals, and meninges. Prolonged intrauterine hypoxia may result in inadequate perfusion of the periventricular white matter, resulting in PVL. Pulmonary arteriole smooth muscle hyperplasia may develop, which predisposes the infant to pulmonary hypertension (see Chapter 122.9). If fetal distress produces gasping, amniotic fluid contents (meconium, squames, lanugo) may be aspirated into the trachea or lungs with subsequent complications, including pulmonary hypertension and pneumothoraces.

Clinical Manifestations

Intrauterine growth restriction with increased vascular resistance may be an indication of chronic fetal hypoxia before the peripartum period. During labor, the fetal heart rate slows and beat-to-beat variability declines. Continuous heart rate recording may reveal a variable or late deceleration pattern (see Chapter 115 , Fig. 115.4). Particularly in infants near term, these signs should lead to the administration of high concentrations of oxygen to the mother and consideration of immediate delivery to avoid fetal death and CNS damage.

At delivery, the presence of meconium-stained amniotic fluid indicates that fetal distress may have occurred. At birth, affected infants may have neurologic impairment and may fail to breathe spontaneously. Pallor, cyanosis, apnea, a slow heart rate, and unresponsiveness to stimulation are also nonspecific initial signs of potential HIE. During the ensuing hours, infants may be hypotonic, may change from a hypotonic to a hypertonic state, or their tone may appear normal (Tables 120.6 and 120.7). Cerebral edema may develop during the next 24 hr and result in profound brainstem depression. During this time, seizure activity may occur; it may be severe and refractory to typical doses of anticonvulsants. Although most often a result of the HIE, seizures in asphyxiated newborns may also be caused by vascular events (hemorrhage, arterial ischemic stroke, or sinus venous thrombosis), metabolic derangements (hypocalcemia, hypoglycemia), CNS infection, and cerebral dysgenesis or genetic disorders (nonketotic hyperglycinemia, vitamin-dependent epilepsies, channelopathies). Conditions that result in neuromuscular weakness and poor respiratory effort may also result secondarily in neonatal hypoxic brain injury and seizure. Such conditions might include congenital myopathies, congenital myotonic dystrophy, or spinal muscular atrophy.

Table 120.6

Poor Predictive Variables for Death/Disability After Hypoxic-Ischemic Encephalopathy

- Low (0–3) 10 min Apgar score
- Need for CPR in the delivery room
- Delayed onset (≥20 min) of spontaneous breathing
- Severe neurologic signs (coma, hypotonia, hypertonia)
- Seizures onset ≤12 hr or difficult to treat
- Severe, prolonged (~7 days) EEG findings including burst suppression pattern
- Prominent MRI basal ganglia/thalamic lesions
- Oliguria/anuria >24 hr
- Abnormal neurologic exam ≥14 days

Table 120.7

Hypoxic-Ischemic Encephalopathy in Term Infants

SIGNS	STAGE 1	STAGE 2	STAGE 3
Level of consciousness	Hyperalert	Lethargic	Stuporous, coma
Muscle tone	Normal	Hypotonic	Flaccid
Posture	Normal	Flexion	Decerebrate
Tendon reflexes/clonus	Hyperactive	Hyperactive	Absent
Myoclonus	Present	Present	Absent
Moro reflex	Strong	Weak	Absent
Pupils	Mydriasis	Miosis	Unequal, poor light reflex
Seizures	None	Common	Decerebration
Electroencephalographic findings	Normal	Low voltage changing to seizure activity	Burst suppression to isoelectric
Duration	<24 hr if progresses; otherwise, may remain normal	24 hr to 14 days	Days to weeks
Outcome	Good	Variable	Death, severe deficits

Adapted from Sarnat HB, Sarnat MS: Neonatal encephalopathy following fetal distress: a clinical and electroencephalographic study, *Arch Neurol* 33:696–705, 1976.Copyright 1976, American Medical Association.

In addition to CNS dysfunction, systemic organ dysfunction is noted in up to 80% of affected neonates. Myocardial dysfunction and cardiogenic shock, persistent pulmonary hypertension, RDS, gastrointestinal perforation, and acute kidney and liver injury are associated with perinatal asphyxia secondary to inadequate perfusion (see Table 120.4).

The severity of neonatal encephalopathy depends on the duration and timing of injury. A clinical grading score first proposed by Sarnat continues to be a useful tool. Symptoms develop over days, making it important to perform serial neurologic examinations (see Tables 120.6 and 120.7). During the initial hours after an insult, infants have a depressed level of consciousness. Periodic breathing with apnea or bradycardia is present, but cranial nerve functions are often spared, with intact pupillary response and spontaneous eye movement. Seizures are common with extensive injury. Hypotonia is also common as an early manifestation of HIE, but it should be distinguished from other causes by history and serial examination.

Diagnosis

MRI is the most sensitive imaging modality for detecting hypoxic brain injury in the neonate. Although such injury can be detected at various times and with varying pulse sequences, diffusion-weighted sequences obtained in the 1st 3-5 days following a presumed sentinel event are optimal for identifying acute injury. (Figs. 120.5 to 120.8 and Table 120.8). Where MRI is unavailable or prevented by clinical instability, CT scans may be helpful in ruling out focal hemorrhagic lesions or large arterial ischemic strokes. Loss of gray-white differentiation and injury to the basal ganglia in more severe HIE can be detected on CT by experienced readers, but CT often misses subtler forms of neonatal hypoxic brain injury. US has limited utility in evaluation of hypoxic injury in the term infant, but it too can be useful for excluding hemorrhagic lesions. Because of factors of size and clinical stability, US is the initial preferred (and sometimes only feasible) modality in evaluation of the preterm infant.

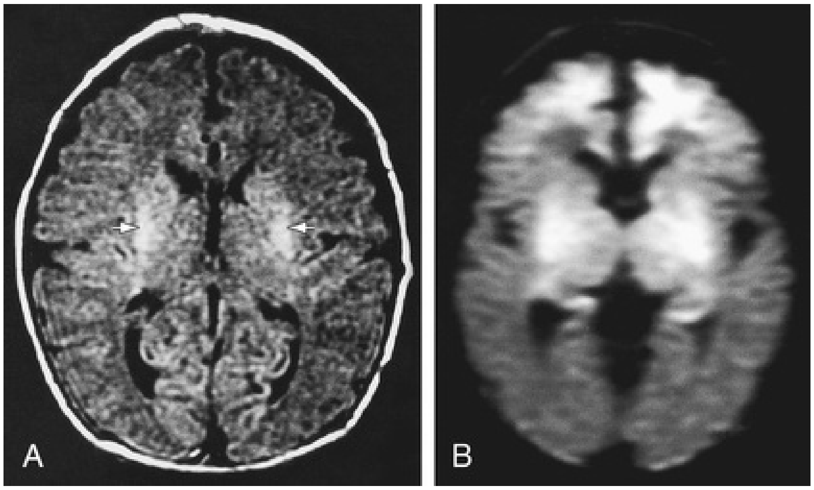

FIG. 120.5 MR images of selective neuronal injury. The infant experienced intrapartum asphyxia and had seizures on the 1st postnatal day. MRI was performed on the 5th postnatal day. A, Axial, fluid-attenuated, inversion recovery image shows increased signal in the putamen bilaterally *(arrows)* but no definite abnormality in the cerebral cortex. B, By contrast, a diffusion-weighted image shows striking increased signal intensity (i.e., decreased diffusion) in the frontal cortex (in addition to a more pronounced basal ganglia abnormality). (From Volpe JJ, editor: *Neurology of the newborn* , ed 5, Philadelphia, 2008, Saunders/Elsevier, p 420.)

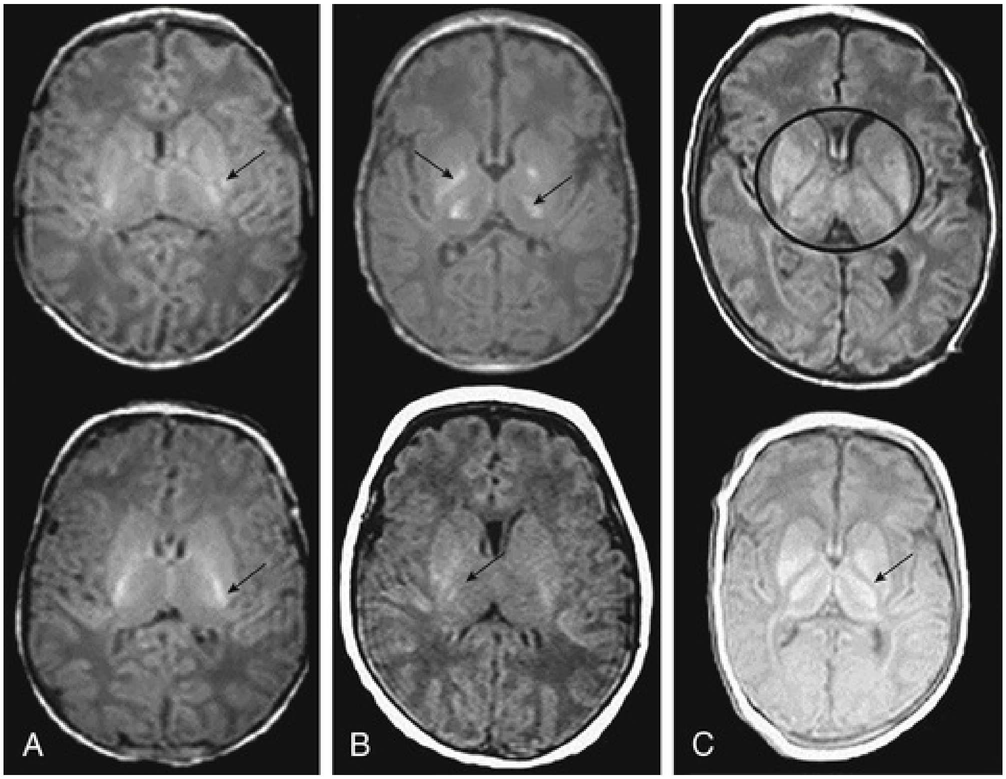

FIG. 120.6 MR images of basal ganglia/thalamic (BG/T) injury and signal intensity. *Top row,* Axial T1-weighted MR images showing A, mild BG/T lesions *(arrow)* ; B, moderate BG/T injury *(arrows)* ; and C, severe BG/T abnormalities *(circled)* . *Bottom row,* Axial T1-weighted MR images showing A, normal signal intensity (SI) in the posterior limb of the internal capsule (PLIC) *(arrow)* ; B, equivocal, asymmetric, and slightly reduced SI in the PLIC *(arrow)* ; and C, abnormal, absent SI in the PLIC *(arrow)* . (From Martinez-Biarge M, Diez-Sebastian J, Rutherford MA, Cowan FM. Outcomes after central grey matter injury in term perinatal hypoxic-ischaemic encephalopathy, *Early Hum Dev* 86:675–682, 2010.)

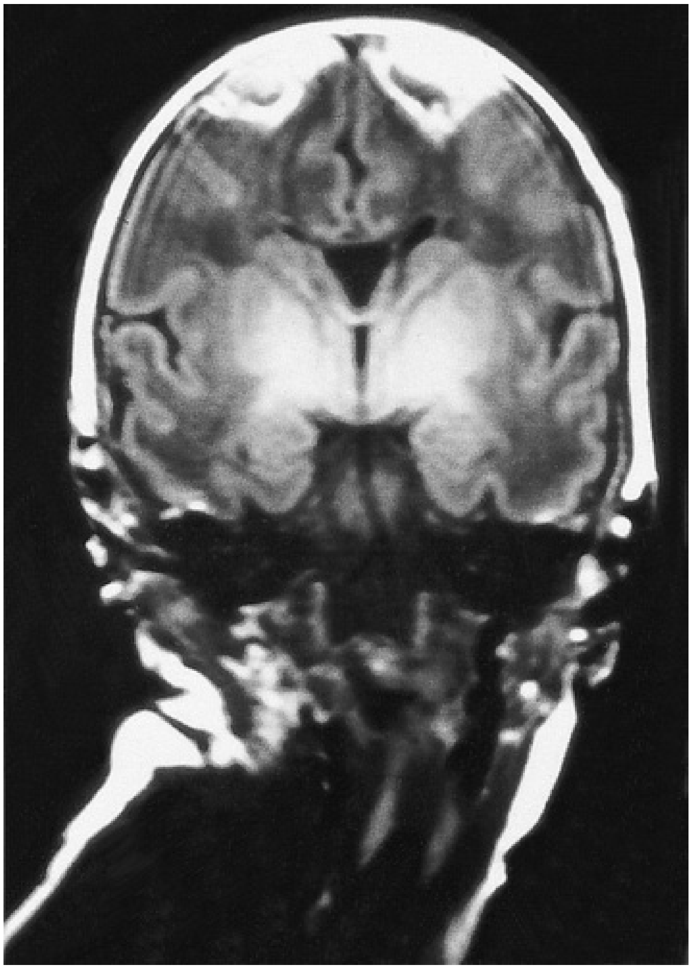

FIG. 120.7 MR image of a parasagittal cerebral injury. Coronal T1-weighted image, obtained on the 5th postnatal day in an asphyxiated term infant, shows striking triangular lesions in the parasagittal areas bilaterally; increased signal intensity is also apparent in the basal ganglia and thalamus bilaterally. (From Volpe JJ, editor: *Neurology of the newborn* , ed 5, Philadelphia, 2008, Saunders/Elsevier, p 421.)

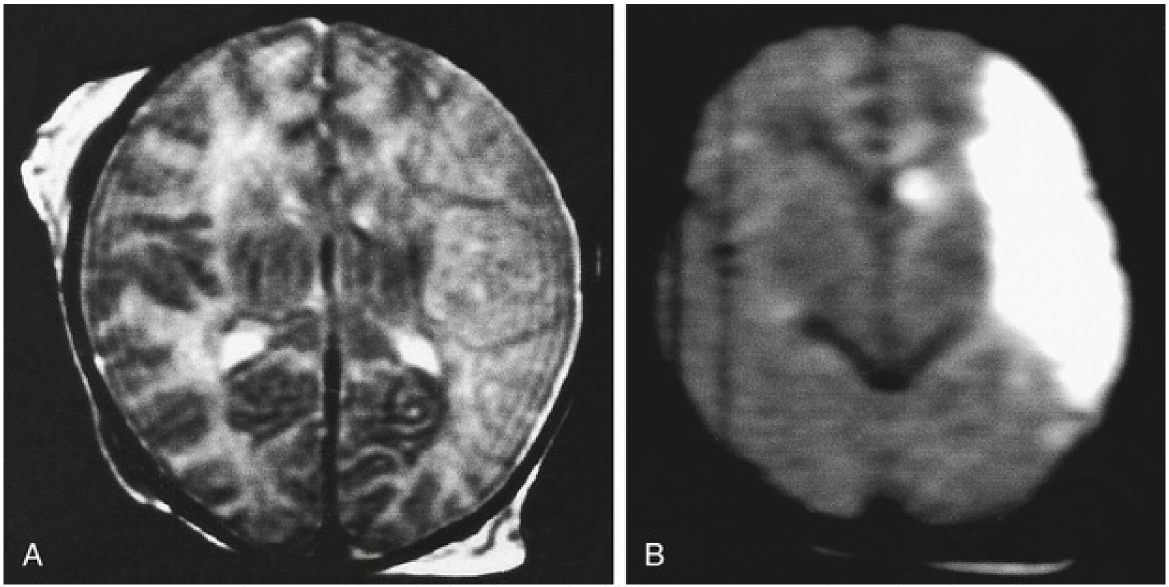

FIG. 120.8 MR images of focal ischemic cerebral injury. MRI was performed on the 3rd postnatal day. A, Axial T2-weighted mage shows a lesion in the distribution of the main branch of the left middle cerebral artery. B, Diffusion-weighted image demonstrates the lesion more strikingly. (From Volpe JJ, editor: *Neurology of the newborn* , ed 5, Philadelphia, 2008, Saunders/Elsevier, p 422.)

Table 120.8

Major Aspects of MRI in Diagnosis of Hypoxic-Ischemic Encephalopathy in the Term Infant

MAJOR CONVENTIONAL MR FINDINGS IN 1ST WEEK
Cerebral cortical gray-white differentiation lost (on T1W or T2W)
Cerebral cortical high signal (T1W and FLAIR), especially in parasagittal perirolandic cortex
Basal ganglia/thalamus, high signal (T1W and FLAIR), usually associated with the cerebral cortical changes but possibly alone with increased signal in brainstem tegmentum in cases of acute severe insult
Parasagittal cerebral cortex, subcortical white matter, high signal (T1W and FLAIR)
Periventricular white matter, decreased signal (T1W) or increased signal (T2W)
Posterior limb of internal capsule, decreased signal (T1W or FLAIR)
Cerebrum in a vascular distribution, decreased signal (T1W), but much better visualized as decreased diffusion (increased signal) on diffusion-weighted MRI
Diffusion-weighted MRI more sensitive than conventional MRI, especially in 1st days after birth, when former shows decreased diffusion (increased signal) in injured areas

FLAIR, Fluid-attenuated inversion recovery; MRI, magnetic resonance imaging; T1W and T2W, T1- and T2-weighted images.

From Volpe JJ, editor: *Neurology of the newborn,* ed 5, Philadelphia, 2008, Elsevier (Table 9-16).

Amplitude-integrated electroencephalography (aEEG) may help to determine which infants are at highest risk for developmental sequelae of neonatal brain injury (Tables 120.9 and 120.10). The aEEG background voltage ranges, signal patterns, and rates of normalization, as assessed at various points in the 1st hours and days of life, can provide valuable prognostic information, with positive predictive value of 85% and negative predictive value of 91–96% for infants who will have adverse neurodevelopmental outcome. Unfortunately, even with recent improvements in technology, aEEG still has difficulty detecting seizures, particularly those that are brief or originate far from the electrodes. Sensitivity of aEEG for seizure detection, when used by a typical reader, is <50%. For this reason, *conventional EEG montage with concurrent video of the patient are preferred for seizure monitoring*.

Table 120.9

Value of Electroencephalography in Assessment of Asphyxiated Term Infants

Detection of severe abnormalities (i.e., CLV, FT, BSP) in 1st hours of life has a positive predictive value of an unfavorable outcome of 80–90%.
Severe abnormalities may improve within 24 hr (~50% of BSP and 10% of CLV/FT).
Rapid recovery of severe abnormalities is associated with a favorable outcome in 60% of cases.
The *combination* of early neonatal neurologic examination and early aEEG enhances the positive predictive value and specificity.

aEEG, Amplitude-integrated encephalography; BSP, burst-suppression pattern; CLV, continuous low voltage; FT, flat trace.

From Inder TE, Volpe JJ: Hypoxic-ischemic injury in the term infant: clinical-neurological features, diagnosis, imaging, prognosis, therapy. In *Volpe's neurology of the newborn,* ed 6, Philadelphia, 2018, Elsevier (Table 20-28).

Table 120.10

Electroencephalographic Patterns of Prognostic Significance in Asphyxiated Term Infants*

ASSOCIATED WITH FAVORABLE OUTCOME
Mild depression (or less) on day 1
Normal background by day 7
ASSOCIATED WITH UNFAVORABLE OUTCOME
Predominant interburst interval >20 sec on any day
Burst-suppression pattern on any day
Isoelectric tracing on any day
Mild (or greater) depression after day 12

* Associations with favorable or unfavorable outcome are generally ≥90%, but the clinical context must be considered.

From Inder TE, Volpe JJ: Hypoxic-ischemic injury in the term infant: clinical-neurological features, diagnosis, imaging, prognosis, therapy. In *Volpe's neurology of the newborn,* ed 6, Philadelphia, 2018, Elsevier (Table 20-26).

Treatment

Therapeutic hypothermia , whether head cooling or systemic cooling (by servo-control to a core rectal or esophageal temperature of 33.5°C [92.3°F] within the 1st 6 hr after birth and maintained for 72 hr), has been shown in various trials to reduce mortality and major neurodevelopmental impairment at 18 mo of age. Infants treated with systemic hypothermia have a lower incidence of cortical neuronal injury on MRI, suggesting systemic hypothermia may result in more uniform cooling of the brain and deeper CNS structures than selective head cooling. The therapeutic effect of hypothermia likely results from decreased secondary neuronal injury achieved by reducing rates of apoptosis and production of mediators known to be neurotoxic, including extracellular glutamate, free radicals, nitric oxide, and lactate. There is also benefit in seizure reduction. The therapeutic benefit of hypothermia noted at 18-22 mo of age is maintained later in childhood. Once established, hypothermia may not alter the prognostic findings on MRI.

Numerous studies seeking ways to extend the benefits of therapeutic hypothermia have been attempted. Assessment of deeper or longer cooling failed to show benefit in short-term outcomes, although longer-term developmental outcomes of that trial are not yet published. Investigations into extending the therapeutic time window of hypothermia initiation beyond 6 hr or offering hypothermia to preterm infants are ongoing.

In addition to extending the benefit of therapeutic hypothermia, there is great interest in augmenting its benefit through other means. High-dose **erythropoietin** given as an adjunct to therapeutic hypothermia shows some promise in decreasing MRI indicators of brain injury and short-term motor outcomes. Further study as well as longitudinal follow-up of the study cohort is warranted to confirm these findings.

Complications of induced hypothermia include thrombocytopenia (usually without bleeding), reduced heart rate, and subcutaneous fat necrosis (sometimes with associated hypercalcemia) as well as the potential for overcooling and the cold injury syndrome. The latter is usually avoided with a servo-controlled cooling system. Therapeutic hypothermia may theoretically alter drug metabolism, prolong the QT interval, and affect the interpretation of blood gases. In clinical practice, these concerns have not been observed.

For treating seizures associated with HIE, **phenobarbital** , the historical first-line drug for neonatal seizures, continues to be used in many instances. It is typically given by intravenous loading dose (20 mg/kg). Additional doses of 5-10 mg/kg (up to 40-50 mg/kg total) may be needed. Phenobarbital levels should be monitored 24 hr after the loading dose has been given and maintenance therapy (5 mg/kg/24 hr) begun. Therapeutic phenobarbital levels are 20-40 µg/mL. Animal models demonstrate decreased neurodevelopmental impact of hypoxic brain injury in animals that received a high-dose prophylactic injection of phenobarbital before onset of therapeutic hypothermia. Whether this benefit translates to humans is controversial.

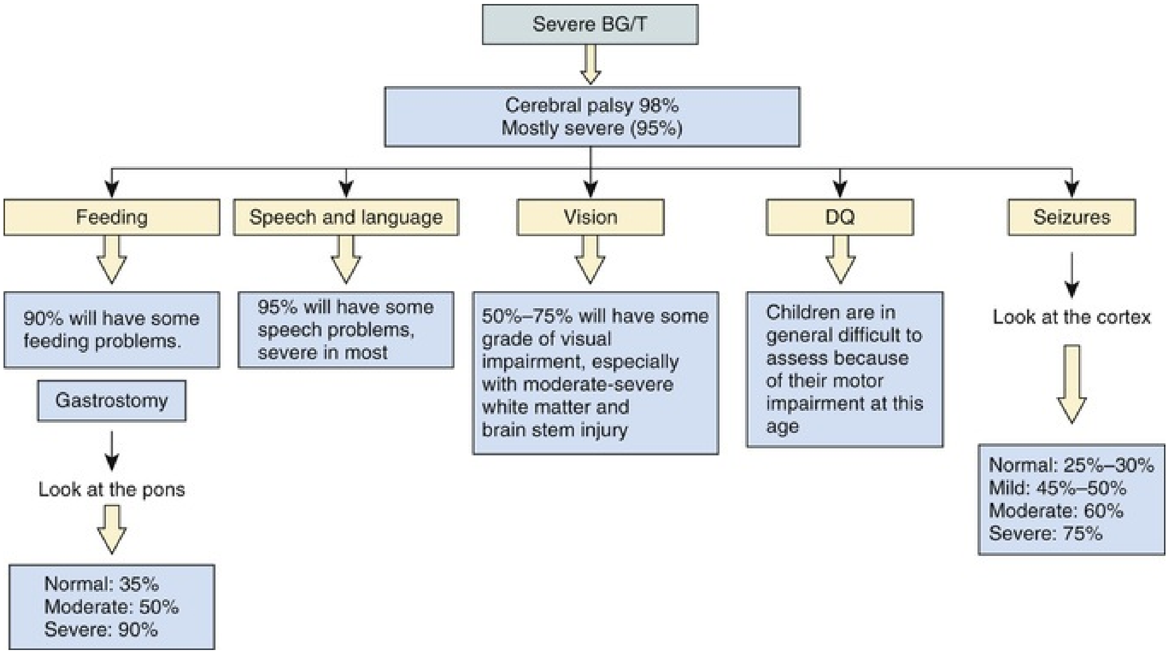
For refractory seizures, there is a high degree of variability regarding choice of 2nd agent. Historically, phenytoin (20 mg/kg loading dose) or lorazepam (0.1 mg/kg) have been preferred, currently the use of **levetiracetam** is preferred (at times even as a first-line agent) as the most used second-line agent. Early reports of administration of levetiracetam in the neonate used low doses, but subsequent pharmacokinetic data suggest that due to the higher volume of distribution created by higher relative body water content in neonates, loading doses should be higher than in older children or adults. Suggested appropriate loading doses may be closer to 60 mg/kg. In addition to levetiracetam and phenytoin, other second- or third-line agents commonly used include midazolam, topiramate, and lidocaine. Pyridoxine should also be attempted, particularly in ongoing refractory seizures with highly abnormal EEG background.

Status epilepticus, multifocal seizures, and multiple anticonvulsant medications during therapeutic hypothermia are associated with a poor prognosis.

Additional therapy for infants with HIE includes supportive care directed at management of organ system dysfunction. Hyperthermia has been associated with impaired neurodevelopment and should be prevented, particularly in the interval between initial resuscitation and initiation of hypothermia. Careful attention to ventilatory status and adequate oxygenation, blood pressure, hemodynamic status, acid-base balance, and possible infection is important. Secondary hypoxia or hypotension from complications of HIE must be prevented. Aggressive treatment of seizures is critical and may necessitate continuous EEG monitoring. In addition, hyperoxia, hypocarbia, and hypoglycemia are associated with poor outcomes, so careful attention to resuscitation, ventilation, and blood glucose homeostasis is essential.

Prognosis

The outcome of HIE, which correlates with the timing and severity of the insult, ranges from complete recovery to death. The prognosis varies depending on the severity of the insult and the treatment. Infants with initial cord or initial blood pH <6.7 have a 90% risk for death or severe neurodevelopmental impairment at 18 mo of age. In addition, infants with Apgar scores of 0-3 at 5 min, high base deficit (>20-25 mmol/L), decerebrate posture, severe basal ganglia/thalamic (BG/T) lesions (Fig. 120.9 ; see also Fig. 120.6), persistence of severe HIE by clinical examination at 72 hr, and lack of spontaneous activity are also at increased risk for death or impairment. These predictor variables can be combined to determine a score that helps with prognosis (see Table 120.6). Infants with the highest risk are likely to die or have severe disability despite aggressive treatment, including hypothermia. Those with intermediate scores are likely to benefit from treatment. In general, severe encephalopathy, characterized by flaccid coma, apnea, absence of oculocephalic reflexes, and refractory seizures, is associated with a poor prognosis (see Table 120.7). Apgar scores alone can also be associated with subsequent risk of neurodevelopmental impairment. At 10 min, each point decrease in Apgar score increases odds of death or disability by 45%. Death or disability occurs in 76–82% of infants with Apgar scores of 0-2 at 10 min. Absence of spontaneous respirations at 20 min of age and persistence of abnormal neurologic signs at 2 wk of age also predict death or severe cognitive and motor deficits.



Severe BG/T
Cerebral palsy 98%
Mostly severe (95%)
Feeding
Speech and language
Vision
DQ
Seizures
90% will have some feeding problems.
Gastrostomy
Look at the pons
Normal: 35%
Moderate: 50%
Severe: 90%
95% will have some speech problems, severe in most
50%–75% will have some grade of visual impairment, especially with moderate-severe white matter and brain stem injury
Children are in general difficult to assess because of their motor impairment at this age
Look at the cortex
Normal: 25%–30%
Mild: 45%–50%
Moderate: 60%
Severe: 75%

FIG. 120.9 Flow chart showing patterns of outcome with severe basal ganglia/thalamic (BG/T) injury. *DQ* , Developmental quotient. (From Martinez-Biarge M, Diez-Sebastian J, Rutherford MA, Cowan FM: Outcomes after central grey matter injury in term perinatal hypoxic-ischaemic encephalopathy, *Early Hum Dev* 86:675–682, 2010.)

The combined use of early conventional EEG or aEEG and MRI offers additional insight in predicting outcome in term infants with HIE (see Table 120.10). EEG or aEEG background characteristics such as pattern, voltage, reactivity, state change, and evolution after acute injury are important predictors of outcome. MRI markers include location of injury, identification of injury by certain pulse sequences, measurement of diffusivity and/or fractional anisotropy, and presence of abnormal metabolite ratios on MR spectroscopy, and all have shown correlation with outcome. There is also growing interest in quantitative measures (volumetric analysis, diffusion tensor imaging) of MRI as potential predictors of outcome. Severe BG/T lesions with abnormal signal in the posterior limb of the internal capsule is highly predictive of the poorest cognitive and motor prognosis (see Fig. 120.9). Normal MRI and EEG findings are associated with a good recovery.

Microcephaly and poor head growth during the 1st year of life also correlate with injury to the basal ganglia and white matter and adverse developmental outcome at 12 mo. All survivors of moderate to severe encephalopathy require comprehensive high-risk medical and developmental follow-up. Early identification of neurodevelopmental problems allows prompt referral for developmental, rehabilitative, and neurologic early intervention services so that the best possible outcomes can be achieved.

Brain death after neonatal HIE is diagnosed from the clinical findings of coma unresponsive to pain, auditory, or visual stimulation; apnea with P_{CO_2} rising from 40 to >60 mm Hg without ventilatory support; and absence of brainstem reflexes (pupillary, oculocephalic, oculovestibular, corneal, gag, sucking) (see Chapter 86). These findings must occur in the absence of hypothermia, hypotension, and elevations of depressant drugs (phenobarbital), which may take days to weeks to be metabolized and cleared completely from the blood. An absence of cerebral blood flow on radionuclide scans and of electrical activity on EEG (electrocerebral silence) is inconsistently observed in clinically brain-dead neonatal infants. Persistence of the clinical criteria for 24 hr in term infants predicts brain death in most asphyxiated newborns. There is no agreement on brain death criteria in preterm infants. Because of inconsistencies and difficulties in applying standard criteria, *no universal agreement has been reached regarding the definition of neonatal brain death.* Consideration of withdrawal of life support should include discussions with the family, the healthcare team, and, if there is disagreement, an ethics committee. The best interest of the infant involves judgments about the benefits and harm of continuing therapy or avoiding ongoing futile therapy.

Spine and Spinal Cord

Cameron W. Thomas, Stephanie L. Merhar

See also Chapter 729 .

Injury to the spine/spinal cord during birth is rare but can be devastating. Strong traction exerted when the spine is hyperextended or when the direction of pull is lateral, or forceful longitudinal traction on the trunk while the head is still firmly engaged in the pelvis, especially when combined with flexion and torsion of the vertical axis, may produce fracture and separation of the vertebrae. Such injuries are most likely to occur when difficulty is encountered in delivering the shoulders in cephalic presentations and the head in breech presentations. The injury occurs most often at the level of the 4th cervical vertebra with cephalic presentations and the lower cervical–upper thoracic vertebrae with breech presentations. Transection of the cord may occur *with or without* vertebral fractures; hemorrhage and edema may produce neurologic signs that are indistinguishable from those of transection, except that they may not be permanent. Areflexia, loss of sensation, and complete paralysis of voluntary motion occur below the level of injury, although the persistence of a withdrawal reflex mediated through spinal centers distal to the area of injury is frequently misinterpreted as representing voluntary motion.

If the injury is severe, the infant, who from birth may be in poor condition because of respiratory depression, shock, or hypothermia, may deteriorate rapidly to death within several hours before any neurologic signs are obvious. Alternatively, the course may be protracted, with symptoms and signs appearing at birth or later in the 1st wk; Horner syndrome, immobility, flaccidity, and associated brachial plexus injuries may not be recognized for several days. Constipation may also be present. Some infants survive for prolonged periods, their initial flaccidity, immobility, and areflexia being replaced after several weeks or months by rigid flexion of the extremities, increased muscle tone, and spasms. Apnea on day 1 and poor motor recovery by 3 mo are poor prognostic signs.

The **differential diagnosis** of neonatal spine/spinal cord injury includes amyotonia congenita and myelodysplasia associated with spina bifida occulta, spinal muscular atrophy (type 0), spinal vascular malformations (e.g., arteriovenous malformation causing hemorrhage or stroke), and congenital structural anomalies (syringomyelia, hemangioblastoma). US or MRI confirms the diagnosis. Treatment of the survivors is supportive, including home ventilation; patients often remain permanently disabled. When a fracture or dislocation is causing spinal compression, the prognosis is related to the time elapsed before the compression is relieved.

Peripheral Nerve Injuries

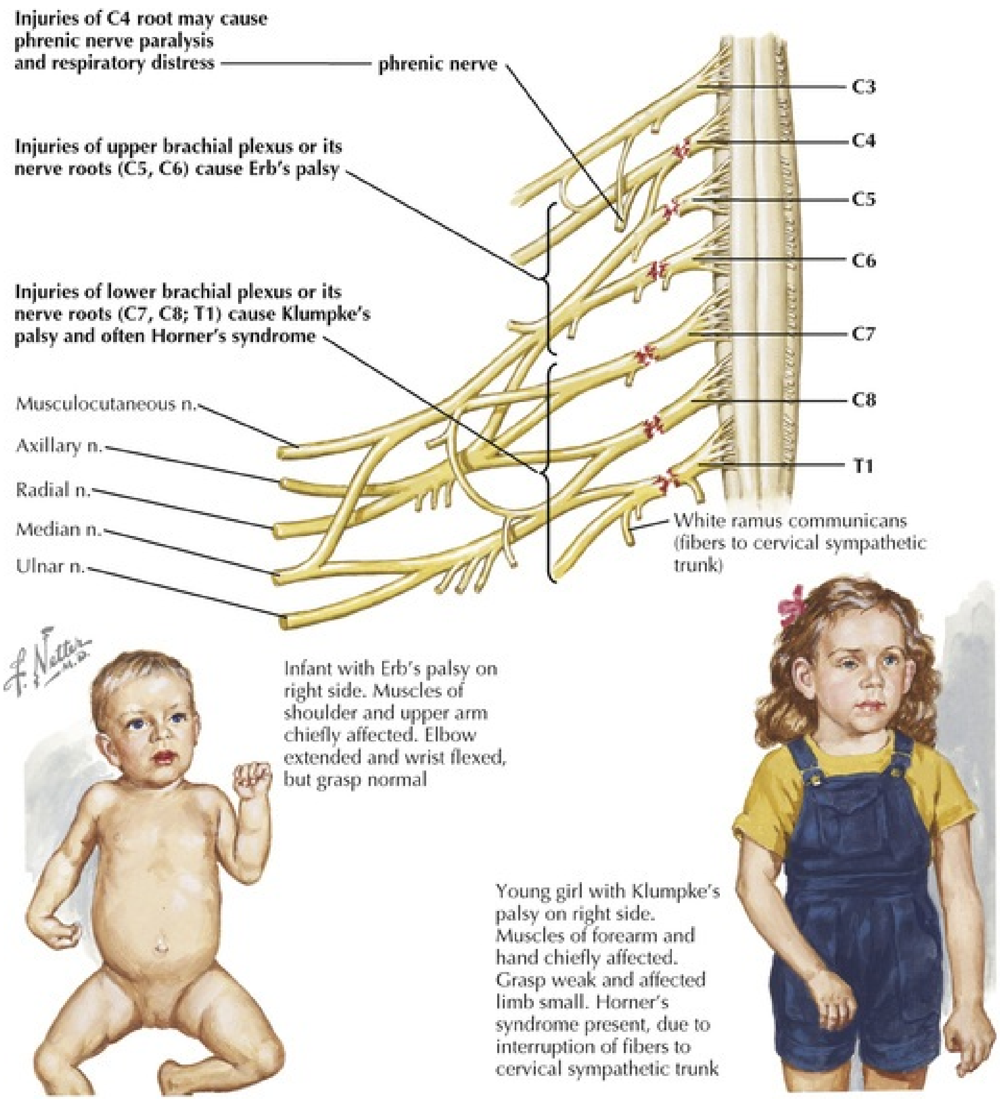
Cameron W. Thomas, Stephanie L. Merhar

See also Chapter 731 .

Brachial Palsy

Brachial plexus injury is a common problem, with an incidence of 0.6-4.6 per 1,000 live births. Injury to the brachial plexus may cause paralysis of the upper part of the arm with or without paralysis of the forearm or hand or, more often, paralysis of the entire arm. These injuries occur in macrosomic infants and when lateral traction is exerted on the head and neck during delivery of the shoulder in a vertex presentation, when the arms are extended over the head in a breech presentation, or when excessive traction is placed on the shoulders. Approximately 45% of brachial plexus injuries are associated with shoulder dystocia.

In **Erb-Duchenne paralysis** the injury is limited to the 5th and 6th cervical nerves. The infant loses the power to abduct the arm from the shoulder, rotate the arm externally, and supinate the forearm. The characteristic position consists of adduction and internal rotation of the arm with pronation of the forearm. Power to extend the forearm is retained, but the biceps reflex is absent; the Moro reflex is absent on the affected side (Fig. 120.10). The outer aspect of the arm may have some sensory impairment. Power in the forearm and hand grasps is preserved unless the lower part of the plexus is also injured; the presence of hand grasp is a favorable prognostic sign. When the injury includes the phrenic nerve, alteration in diaphragmatic excursion may be observed with US, fluoroscopy, or as asymmetric elevation of the diaphragm on chest radiograph.



Injuries of C4 root may cause phrenic nerve paralysis and respiratory distress
phrenic nerve
Injuries of upper brachial plexus or its nerve roots (C5, C6) cause Erb's palsy
Injuries of lower brachial plexus or its nerve roots (C7, C8; T1) cause Klumpke's palsy and often Horner's syndrome

Young girl with Klumpke's palsy on right side. Muscles of forearm and hand chiefly affected. Grasp weak and affected limb small. Horner's syndrome present, due to interruption of fibers to cervical sympathetic trunk

FIG. 120.10 **Schematic representation of the brachial plexus with its terminal branches. The major sites of brachial plexus injury are shown. (Courtesy of Netter Images, Image ID 19943. www.netterimages.com .)**

Klumpke paralysis is a rare form of brachial palsy in which injury to the 7th and 8th cervical nerves and the 1st thoracic nerve produces a paralyzed hand and ipsilateral ptosis and miosis (**Horner syndrome**) if the sympathetic fibers of the 1st thoracic root are also injured. Mild cases may not be detected immediately after birth. Differentiation must be made from cerebral injury; from fracture, dislocation, or epiphyseal separation of the humerus; and from fracture of the clavicle. MRI demonstrates nerve root rupture or avulsion.

Most patients have full recovery. If the paralysis was a result of edema and hemorrhage around the nerve fibers, function should return within a few months; if it resulted from laceration, permanent damage may result. Involvement of the deltoid is usually the most serious problem and may result in **shoulder drop** secondary to muscle atrophy. In general, paralysis of the upper part of the arm has a better prognosis than paralysis of the lower part.

Treatment consists of initial conservative management with monthly follow-up and a decision for surgical intervention by 3 mo if function has not improved. Partial immobilization and appropriate positioning are used to prevent the development of contractures. In upper arm paralysis, the arm should be abducted 90 degrees with external rotation at the shoulder, full supination of the forearm, and slight extension at the wrist with the palm turned toward the face. This position may be achieved with a brace or splint during the 1st 1-2 wk. Immobilization should be intermittent throughout the day while the infant is asleep and between feedings. In lower arm or hand paralysis, the wrist should be splinted in a neutral position and padding placed in the fist. When the entire arm is paralyzed, the same treatment principles should be followed. Gentle massage and range-of-motion exercises may be started by 7-10 days of age. Infants should be closely monitored with active and passive corrective exercises. If the paralysis persists without improvement for 3 mo, neuroplasty, neurolysis, end-to-end anastomosis, and nerve grafting offer hope for partial recovery.

The type of treatment and the prognosis depend on the mechanism of injury and the number of nerve roots involved. The mildest injury to a peripheral nerve (**neurapraxia**) is caused by edema and heals spontaneously within a few weeks. **Axonotmesis** is more severe and is a consequence of nerve fiber disruption with an intact myelin sheath; function usually returns in a few months. Total disruption of nerves (**neurotmesis**) or root avulsion is the most severe, especially if it involves C5-T1; microsurgical repair may be indicated. Fortunately, most (75%) injuries are at the root level C5-C6, involve neurapraxia and axonotmesis, and should heal spontaneously. Botulism toxin may be used to treat biceps-triceps co-contractions.

Phrenic Nerve Paralysis

Phrenic nerve injury (3rd, 4th, 5th cervical nerves) with diaphragmatic paralysis must be considered when cyanosis and irregular and labored respirations develop. Such injuries, usually unilateral, are associated with ipsilateral upper brachial plexus palsies in 75% of cases. Because breathing is thoracic in type, the abdomen does not bulge with inspiration. Breath sounds are diminished on the affected side. The thrust of the diaphragm, which may often be felt just under the costal margin on the normal side, is absent on the affected side. The diagnosis is established by US or fluoroscopic examination, which reveals elevation of the diaphragm on the paralyzed side and seesaw movements of the 2 sides of the diaphragm during respiration. It may also be apparent on chest or abdominal radiograph.

Infants with phrenic nerve injury should be placed on the involved side and given oxygen if necessary. Some may benefit from pressure introduced by continuous positive airway pressure (CPAP) to expand the paralyzed hemidiaphragm. In extreme cases, mechanical ventilation cannot be avoided. Initially, intravenous feedings may be needed; later, progressive gavage or oral feeding may be started, depending on the infant's condition. Pulmonary infections are a serious complication. If the infant fails to demonstrate spontaneous recovery in 1-2 mo, surgical plication of the diaphragm may be indicated.

Facial Nerve Palsy

Facial palsy is usually a peripheral paralysis that results from pressure over the facial nerve in utero, during labor, or from forceps use during delivery. Rarely, it may result from nuclear agenesis of the facial nerve.

Peripheral facial paralysis is flaccid and, when complete, involves the entire side of the face, including the forehead. When the infant cries, movement occurs only on the nonparalyzed side of the face, and the mouth is drawn to that side. On the affected side the forehead is smooth, the eye cannot be closed, the nasolabial fold is absent, and the corner of the mouth droops. **Central facial paralysis** spares the forehead (e.g., forehead wrinkles will still be apparent on the affected side) because the nucleus that innervates the upper face has overlapping dual innervation by corticobulbar fibers originating in bilateral cerebral hemispheres. The infant with central facial paralysis usually has other manifestations of intracranial injury, most often 6th nerve palsy from the proximity of the 6th and 7th cranial nerve nuclei in the brainstem. Prognosis depends on whether the nerve was injured by pressure or the nerve fibers were torn; improvement occurs within a few weeks in the former case. Care of the exposed eye is essential. Neuroplasty may be indicated when the paralysis is persistent. Facial palsy may be confused with absence of the depressor muscles of the mouth, which is a benign problem or with variants of Möbius syndrome.

Other peripheral nerves are seldom injured in utero or at birth except when they are involved in fractures or hemorrhage.

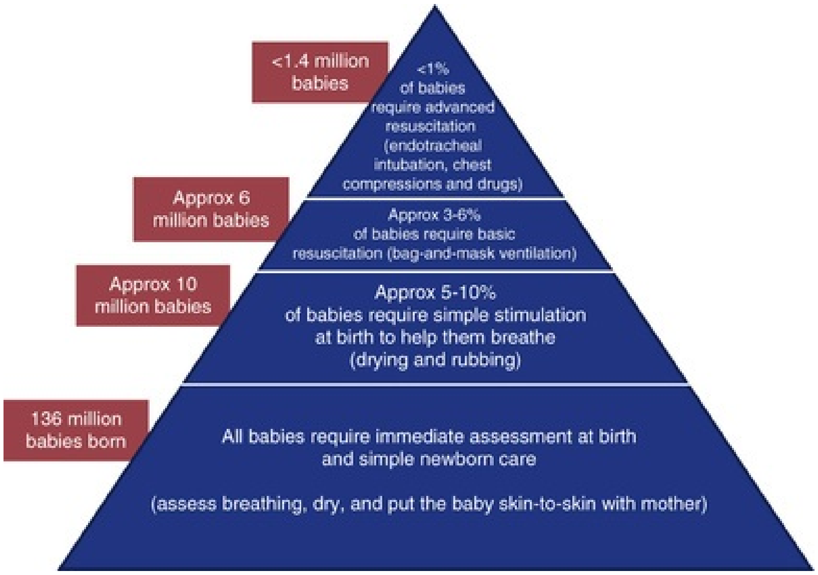
CHAPTER 121

Neonatal Resuscitation and Delivery Room Emergencies

Jennifer M. Brady, Beena D. Kamath-Rayne

Most infants complete the transition to extrauterine life without difficulty; however, a small proportion require resuscitation after birth (Fig. 121.1). For a newborn infant, the need for resuscitation is often caused by a problem with respiration leading to inadequate ventilation. This is in contrast to an adult cardiac arrest, which is usually caused by inadequate circulation. The goals of neonatal resuscitation are to reestablish adequate spontaneous respirations, obtain adequate cardiac output, and prevent the morbidity and mortality associated with hypoxic-ischemic tissue (brain, heart, kidney) injury. High-risk situations should be *anticipated* from pregnancy history and labor. Improved perinatal care and prenatal diagnosis of fetal anomalies allow for appropriate maternal transports for high-risk deliveries. Infants who are born limp, cyanotic, apneic, or pulseless require immediate resuscitation before assignment of the 1 min Apgar score. Rapid and appropriate resuscitative efforts improve the likelihood of preventing brain damage and achieving a successful outcome.



<1.4 million babies
<1% of babies require advanced resuscitation (endotracheal intubation, chest compressions and drugs)
Approx 6 million babies
Approx 3-6% of babies require basic resuscitation (bag-and-mask ventilation)
Approx 10 million babies
Approx 5-10% of babies require simple stimulation at birth to help them breathe (drying and rubbing)
136 million babies born
All babies require immediate assessment at birth and simple newborn care
(assess breathing, dry, and put the baby skin-to-skin with mother)

FIG. 121.1 **Estimates of infants requiring resuscitation at birth. (From Wall SN, Lee ACC, Niermeyer S, et al: Neonatal resuscitation in low-resource settings: what, who, and how to overcome challenges to scale up? *Int J Gynaecol Obstet* 107:S47–S64, 2009, Fig 1.)**

Neonatal Resuscitation

See also Chapter 81 .

Guidelines for the **Neonatal Resuscitation Program (NRP)** are based on recommendations from the International Liaison Committee on Resuscitation Consensus on Treatment Recommendations. These recommendations propose an *integrated* assessment/response approach for the initial evaluation of an infant, consisting of simultaneous assessment of infant general appearance and risk factors. The fundamental principles include evaluation of the airway and establishing effective respirations and adequate circulation. The guidelines also highlight the assessment and response to the neonatal heart rate.

Before the birth of a baby, sufficient preparation for the birth should occur. At least 1 individual capable of neonatal resuscitation should be present at the delivery, and if advanced resuscitation is anticipated, more individuals should be available to help. Necessary equipment should be available, which routinely includes: a warmer bed, blankets, infant hat, stethoscope, bulb suction, suction catheter with wall suction, bag-mask device, oxygen source with blender, pulse oximeter, laryngoscope with blade, and endotracheal tubes (ETTs). Based on the specific details of the pregnancy, further equipment that may be needed should be anticipated and readily available. The equipment should be checked to make sure it is functioning appropriately. Team members should introduce themselves, define a team leader, assign roles for the resuscitation, and discuss what actions they will take during the resuscitation. For complex resuscitations, there may be 1 individual whose sole job is to keep track of time and record what interventions are taken, both to ensure the correct steps are performed in a timely manner and to review during debriefing later.

Immediately after birth, all term infants should be dried, warmed, and stimulated. If the infant does not need resuscitation, these steps can occur on the mother's abdomen while delayed cord clamping is taking place. Simultaneously, the infant's tone, respiratory effort, and heart rate should be assessed (Fig. 121.2).

FIG. 121.2 **Newborn resuscitation algorithm. CPAP, Continuous positive airway pressure; ETT, endotracheal tube; HR, heart rate; IV, intravenous; PPV, positive pressure ventilation; UVC, umbilical venous catheter. *At this point in resuscitation 100% oxygen is instituted. (From Wyckoff MH, Aziz K, Escobedo MB, et al. Part 13. Neonatal resuscitation: 2015 American Heart Association guidelines update for cardiopulmonary resuscitation and emergency cardiovascular care, *Circulation* 132(Suppl 2):S542–S560, 2015, Fig 1.)**

Failure to initiate or sustain respiratory effort is fairly common at birth, with

5–10% of births requiring some intervention. Infants with **primary apnea** respond to stimulation by establishing normal breathing. Infants with **secondary apnea** require some ventilatory assistance in order to establish spontaneous respiratory effort. Secondary apnea usually originates in the central nervous system (CNS) as a result of asphyxia or peripherally because of neuromuscular disorders. The lungs in infants affected by conditions such as pulmonary hypoplasia and prematurity may be noncompliant, and initial efforts to begin respirations may be inadequate to initiate sufficient ventilation.

The steps in neonatal resuscitation follow the ABCs: **A,** anticipate and establish a patent **airway** by positioning the baby with the head slightly extended, sniffing position, and suctioning if secretions are blocking the airway; **B,** initiate **breathing** first by using tactile stimulation, followed by positive pressure ventilation (PPV) with a bag-mask device and ETT insertion should the baby remain apneic or PPV is not achieving effective ventilation; and **C,** maintain the **circulation** with chest compressions and medications, if needed. Fig. 121.2 outlines the steps to follow for immediate neonatal evaluation and resuscitation.

In term infants after stimulation, if no respirations are noted, or if the heart rate is <100 beats/min, PPV should be given through a tightly fitted and appropriately sized bag-mask device. PPV should be initiated at pressures of approximately 20 cm H_2O at a rate of 40-60 breaths/min initially with 21% fraction of inspired oxygen (FIO_2) for full-term infants.

At the same time PPV is initiated, a pulse oximeter should be placed on the right hand (preductal) and cardiac leads placed on the chest. In the past the recommended inspired gas for neonatal resuscitation had been 100% oxygen. However, resuscitation with room air in *term infants* is equally effective and may reduce the risk of hyperoxia, which is associated with decreased cerebral blood flow and generation of oxygen free radicals. Room air is the preferred *initial gas* for neonatal resuscitation in term infants. O_2 concentration administered should then be titrated as needed to obtain expected O_2 saturations in a term infant after birth, as defined by normal reference range by minute of life (see Fig. 121.2).

Successful and effective ventilation is signified by adequate chest rise, symmetric breath sounds, improved pink color, heart rate >100 beats/min, increasing O_2 saturation, spontaneous respirations, and improved tone. *If after 30 sec of providing PPV there are no signs of effective ventilation, corrective steps should be performed to improve ventilation.* The 6 ventilation corrective steps can be remembered with the mnemonic **MRSOPA** : *m* ask readjustment, *r* eposition the head, *s* uction mouth and nose, *o* pen the mouth, *p* ressure increase, and *a* lternative airway).

In infants with severe respiratory depression who do not respond to PPV by bag-mask, after corrective steps have been taken, endotracheal intubation should be performed. For infants with an otherwise normal airway weighing <1,000 g, ETT size is usually 2.5 mm; for infants 1,000-2,000 g, 3 mm; and for infants >2,000 g, 3.5 mm. A general rule for depth of insertion from upper lip in centimeters is 6 plus infant's weight in kilograms. Poor response to ventilation may be a result of a loosely fitted mask, poor positioning of the ETT, esophageal intubation, airway obstruction, insufficient pressure, pleural effusions, pneumothorax, excessive air in the stomach leading to abdominal competition, asystole, hypovolemia, diaphragmatic hernia, or prolonged intrauterine asphyxia. Various devices to detect exhaled CO_2 and to confirm accurate ETT placement are available. A laryngeal mask airway may also be an effective tool to establish an airway, especially if PPV is ineffective and intubation attempts are unsuccessful.

The underlying cause for the vast majority of infants having a low heart rate is not a primary cardiac cause, but instead the result of **ineffective ventilation** . Therefore, if the heart rate remains <60 beats/min after 60 sec of PPV with corrective MRSOPA steps, the infant should be intubated (if not already done) to achieve effective ventilation. *Once the infant is intubated, if the heart rate remains <60 beats/min, chest compressions should be initiated with continued ventilation, and* F_{IO_2} *increased to 100%.* Chest compressions should be initiated over the lower third of the sternum at a rate of 90/min. The ratio of compressions to ventilation is 3 : 1 (90 compressions:30 breaths). A provider, separate from the person providing ventilation, is needed to administer chest compressions. Two different techniques exist for performing chest compressions: the thumb technique and the 2-finger technique. For the *thumb technique* the tips of both thumbs are used to depress the sternum, with the fingers on each side encircling the chest; this is the preferred method to administer chest compressions, because it has been shown to achieve a higher blood pressure, increase coronary perfusion, and result in less fatigue. The *2-finger technique* involves depressing the sternum with the tips of the middle finger and index finger while supporting the back with the palm of the other hand. In infants, regardless of whether an alternative airway has been secured, chest compressions are always coordinated with PPV. Chest compressions should continue uninterrupted for 45-60 sec before reassessing heart rate to determine next steps.

Medications are rarely required, but **epinephrine** should be administered when the heart rate is <60 beats/min after 60 sec of combined ventilation and chest compressions or during asystole. Persistent **bradycardia** in neonates is usually attributable to hypoxia resulting from respiratory arrest and often responds rapidly to effective ventilation alone. Persistent bradycardia despite what appears to be adequate resuscitation suggests inadequate ventilation or more severe cardiac compromise.

The umbilical vein can generally be readily cannulated and is the preferred method for administration of medications and volume expanders during neonatal resuscitation (Fig. 121.3). The ETT may be used for the administration of epinephrine if intravenous access is not yet available. Epinephrine (1 : 10,000 solution at 0.1-0.3 mL/kg *intravenously* or 0.5-1 mL/kg *intratracheally*) is given for asystole or for continued heart rate <60 beats/min after 60 sec of combined resuscitation. The dose may be repeated every 3-5 min. If adequate resuscitation continues for 10 min without a detectable heart rate, it is reasonable to stop resuscitative efforts.

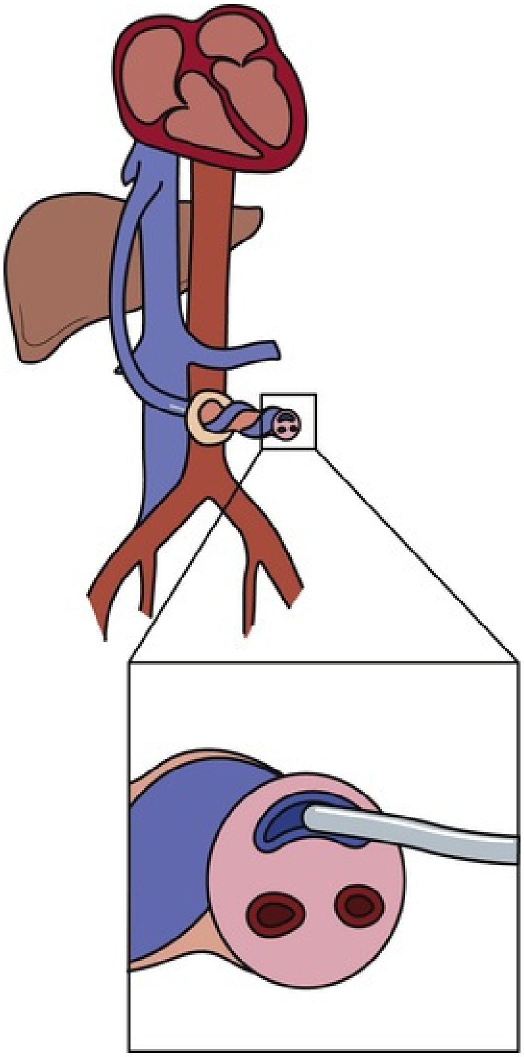

FIG. 121.3 Emergently placed umbilical venous catheter suitable for neonatal resuscitation.

Resuscitation of the Preterm Infant

Resuscitation of the preterm infant should follow the same steps as a term infant, with some special considerations. Whereas resuscitation of term infants should start with room air, resuscitation of most preterm infants can be initiated with slightly higher FIO_2, 21–30%. Pulse oximetry of the preductal (right) hand should be used to titrate O_2 concentrations for targeted saturations per the NRP algorithm (see Fig. 121.2).

Special attention should be paid to *keeping the preterm infant warm in the delivery room*. Quality improvement projects have initiated bundles to improve admission temperatures of preterm infants to the neonatal intensive care unit (NICU) and have included such interventions as higher ambient temperatures in the delivery room, immediate placement of preterm infants into a plastic bag or under plastic wrap rather than drying, and exothermic mattress for resuscitation and transport of the preterm infant.

Delayed cord clamping for 1-3 min can be performed in both preterm and term infants but is especially recommended for preterm infants. Benefits to term infants include higher hemoglobin levels at birth with improved iron stores in the 1st several mo of life. Additional benefits for preterm infants include improved hemodynamic stability, decreased need for inotropic support, decreased need for transfusions, and decreased risk of necrotizing enterocolitis and intraventricular hemorrhage. The American College of Obstetricians and Gynecologists (ACOG) recommends at least 30-60 sec of delayed cord clamping after birth for vigorous term and preterm infants. It is unclear, however, whether delayed cord clamping should be continued when an infant requires resuscitation. Studies are investigating whether the onset of respirations before delayed cord clamping is beneficial for both hemodynamic stability and decreased neonatal mortality.

Special Circumstances in the Delivery Room

Meconium

Meconium staining of the amniotic fluid may be an indication of fetal stress. Previously, the presence of meconium-stained amniotic fluid in a *nonvigorous* infant required tracheal intubation to attempt to aspirate meconium below the cords; NRP recommendations (7th edition) no longer support this practice. If an infant is born through meconium-stained amniotic fluid, it does not matter whether they are vigorous or nonvigorous; the infant should receive the same initial steps of basic resuscitation and should be assessed as any other infant. Tracheal intubation may delay the initiation of effective PPV, which will help the baby to breathe and achieve effective gas exchange.

Placental Abruption

Placental abruption (abruptio placentae) at birth can lead to massive fetal blood loss and a hypovolemic, anemic infant at delivery. Infants can present pale and apneic with poor tone, decreased perfusion, and bradycardia. In addition to performing routine neonatal resuscitation, when an infant is suspected to be symptomatic from a placental abruption, an emergency low-lying umbilical venous catheter (UVC) should be placed and emergent type O Rh-negative blood should be obtained. In acute blood loss, the blood should be administered as quickly as possible in 10 mL/kg aliquots in the delivery room**.** Adequate communication between obstetrics and pediatrics regarding suspected abruption is crucial to early recognition and treatment of the infant.

Neonatal Encephalopathy

Infants with neonatal encephalopathy are born with abnormal neurologic function, including level of consciousness, muscle tone, and reflexes. Although there are many possible etiologies, when symptoms are accompanied by a defined perinatal event such as cord prolapse or placental abruption, **hypoxic-ischemic brain injury** is the presumed cause. These infants are often born with impaired respiratory drive. In addition to routine neonatal resuscitation, term infants with concern for neonatal encephalopathy should be passively cooled in the delivery room by not turning on the warmer bed. After initial resuscitation and stabilization, a more thorough neurologic examination can be performed to assess if the infant meets formal criteria for moderate to severe encephalopathy in order to proceed with whole body cooling (see Chapter 120.4).

Airway Obstruction

Hypoplasia of the mandible with posterior displacement of the tongue may result in upper airway obstruction (Pierre Robin, Stickler, DiGeorge, and other syndromes; see Chapter 337). Symptoms may sometimes be temporarily relieved by pulling the tongue or mandible forward or placing the infant in the prone position. Other rare causes of upper airway obstruction at birth include laryngeal atresia or stenosis, teratomas, hygromas, and oral tumors. Critical fetal and then neonatal airway obstruction represents an emergency in the delivery room. High-risk perinatal care has led to the more frequent prenatal diagnosis of these disorders. When diagnosed prenatally, planning can identify the location of delivery and interventions available at delivery. The **ex utero intrapartum treatment (EXIT)** procedure allows time to secure the airway in an infant known prenatally to have critical airway obstruction, before the infant is separated from the placenta (Fig. 121.4). Uteroplacental gas exchange is maintained throughout the procedure.

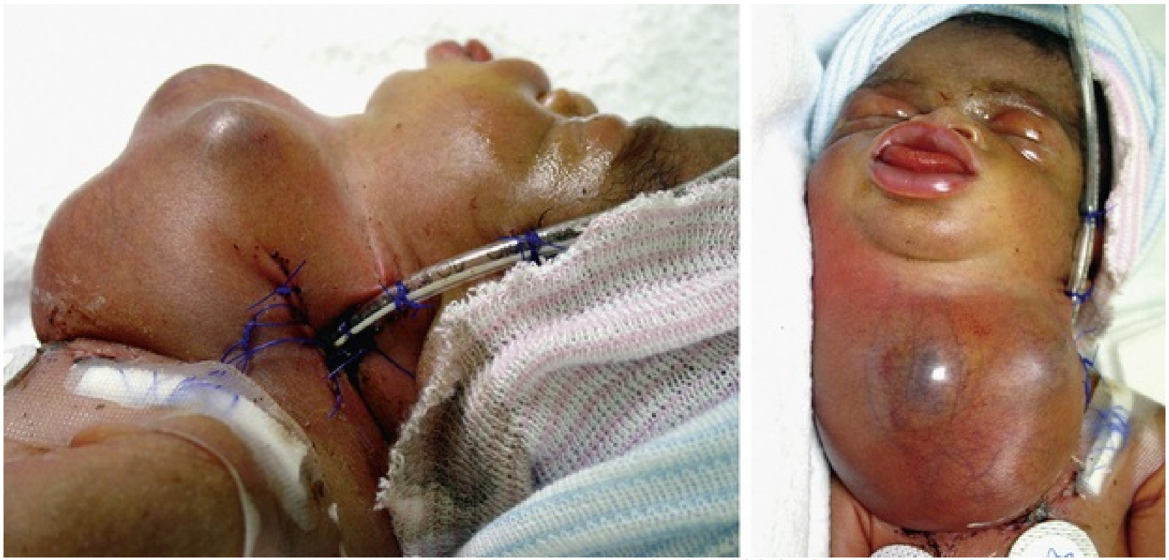

FIG. 121.4 **EXIT procedure. Baby with teratoma and critical high airway obstruction syndrome. Trachea is displaced to the lateral neck. (Courtesy of Dr. Mark Wulkan, Pediatric Surgery, Emory University.)**

Respiratory Distress

Both congenital abnormalities and iatrogenic causes secondary to required resuscitation can contribute to respiratory distress in the neonate. A **scaphoid abdomen** suggests a diaphragmatic hernia**,** as does asymmetry in contour or movement of the chest. An infant with a known diaphragmatic hernia should be immediately intubated in the delivery room and an orogastric tube placed to avoid gaseous distention of the bowel from crying or PPV. The infant should then be transferred to a tertiary referral center for surgical evaluation and treatment (see Chapter 122.1).

In infants with a prenatal diagnosis of hydrops, pleural effusions may be present at delivery, preventing adequate lung expansion and gas exchange. Similarly, infants requiring PPV in the delivery room are at risk for developing a **pneumothorax** . Infants with pulmonary hypoplasia or meconium-stained fluid are at increased risk of this complication. Clinically, infants with a pleural effusion or pneumothorax present with respiratory distress and hypoxia, with *diminished* breath sounds on the affected side. Transillumination may be helpful to confirm the diagnosis. Emergency evacuation of a pneumothorax or pleural effusion without radiographic confirmation is indicated in an infant who is unresponsive to resuscitation efforts and has asymmetric breath sounds, bradycardia, and cyanosis. An angiocatheter attached to a stopcock and syringe should be used for evacuation. For a pneumothorax, an angiocatheter should be inserted perpendicular to the chest wall above the rib in the 2nd intercostal space in the midclavicular line and air evacuated. For a pleural effusion, with the infant in the supine position, the angiocatheter should be inserted in the 4th or 5th intercostal space in the anterior axillary line and directed posteriorly to evacuate the fluid (see Chapter 122).

Abdominal Wall and Neural Tube Defects

Appropriate management of patients with abdominal wall defects (omphalocele, gastroschisis) in the delivery room prevents excessive fluid loss and minimizes the risk for injury to the exposed viscera. **Gastroschisis** is the more common defect, and typically the intestines are not covered by a membrane. The exposed intestines should be gently placed in a sterile clear plastic bag after delivery. A membrane often covers an **omphalocele** , and care should be taken to prevent its rupture. A nasogastric tube should be placed and the infant transferred to a tertiary referral center for surgical consultation and evaluation for associated anomalies (see Chapter 125).

Similarly, infants born with neural tube defects such as a **myelomeningocele** need special care at delivery to protect the exposed neural tube tissue from trauma and infection; infants should be placed on their side or abdomen for resuscitation. The site of the neural tube defect should be covered with a moist sterile dressing to prevent drying and infection. The infant should then be transferred to a tertiary referral center for surgical evaluation and treatment.

Injury During Delivery

Central Nervous System

Both extracranial and intracranial birth injuries can be seen in infants after birth. **Extracranial** lesions include cephalohematoma, caput succedaneum, and subgaleal hemorrhage. **Intracranial** birth injuries include subdural hemorrhage, subarachnoid hemorrhage, and epidural hematoma. The most common intracranial injury experienced at birth is **subdural hemorrhage** , with increasing incidence seen with instrument-assisted vaginal deliveries (see Chapters 120.1 and 120.2).

Fractures

The clavicle is the most frequently fractured bone during labor and delivery. It is particularly vulnerable to injury with difficult delivery of the shoulder in the setting of **shoulder dystocia** , as well as with extended arms in breech deliveries. In the treatment of shoulder dystocia, the obstetrician may intentionally fracture the clavicle so that delivery can proceed. Symptoms of a clavicular fracture include an infant not moving the arm freely on the affected side, palpable crepitus or bony irregularity, and asymmetric or absent Moro reflex on the affected side. The prognosis for this fracture is excellent. Often, no specific treatment is needed, although in some cases the arm and shoulder on the affected side are immobilized for comfort.

Fractures of the long bones are fairly rare. Injuries often present with absent spontaneous movement of the extremity. Associated nerve involvement may also occur. Treatment involves immobilization of the affected extremity with a splint and orthopedic follow-up.

Brachial Plexus Injuries

Brachial plexus injuries result from stretching and tearing of the brachial plexus (spinal roots C5-T1) at delivery. Although shoulder dystocia is associated with an increased risk of brachial plexus injury, it can also occur during a routine delivery (see Chapter 120.6).

Ongoing Care After Resuscitation

The “golden hour” after a baby's birth should emphasize effective neonatal resuscitation, postresuscitation care, prevention of hypothermia, immediate breastfeeding if able, prevention of hypoglycemia, and therapeutic hypothermia for cases of moderate to severe neonatal encephalopathy (birth asphyxia). After supportive measures have stabilized the infant's condition, a specific diagnosis should be established and appropriate continuing treatment instituted.

After initial resuscitation and stabilization, an infant with a significant metabolic acidosis may potentially require further treatment with sodium bicarbonate and/or 10 mL/kg of volume expander. If infection is suspected, appropriate antibiotics should be started as soon as possible. Severe neonatal encephalopathy may also depress myocardial function and cause cardiogenic shock despite the recovery of heart and respiratory rates. Fluids and dopamine or epinephrine as a continuous infusion should be started after initial resuscitation efforts, to improve cardiac output in an infant with poor peripheral perfusion, weak pulses, hypotension, tachycardia, or poor urine output. Regardless of the severity of neonatal encephalopathy or the response to resuscitation, asphyxiated infants should be monitored closely for signs of multiorgan hypoxic-ischemic tissue injury (see Chapter 120.4).

CHAPTER 122

Respiratory Tract Disorders

Shawn K. Ahlfeld

Respiratory disorders are the most frequent cause of admission for neonatal intensive care in both term and preterm infants. Signs and symptoms of respiratory distress include cyanosis, expiratory grunting, nasal flaring, retractions, tachypnea, decreased breath sounds with or without rales and/or rhonchi, and pallor. A wide variety of pathologic lesions may be responsible for respiratory disturbances, including pulmonary, airway, cardiovascular, central nervous system, infectious, and other disorders (Fig. 122.1).

FIG. 122.1 **Neonate with acute respiratory distress. BP, Blood pressure; CVS, cardiovascular system; HCT, hematocrit. (From Battista MA, Carlo WA: Differential diagnosis of acute respiratory distress in the neonate. In Frantz ID, editor: *Tufts University of School of Medicine and Floating Hospital for Children reports on neonatal respiratory diseases,* vol 2, issue 3, Newtown, PA, 1992, Associates in Medical Marketing Co.)**

It is occasionally difficult to distinguish respiratory from nonrespiratory etiologies on the basis of clinical signs alone. Signs of respiratory distress are an indication for a physical examination and diagnostic evaluation, including determination of ventilation by arterial blood gases and oxygenation by pulse oximetry, and assessment of lung fields with chest radiography. Timely and appropriate therapy is essential to improve outcome.

122.1

Transition to Pulmonary Respiration

Shawn K. Ahlfeld

Keywords

fetal lung fluid
functional residual capacity
positive pressure ventilation
surfactant
periodic breathing

Successful establishment of adequate lung function at birth depends on airway patency, functional lung development, and maturity of respiratory control. *Fetal lung fluid* must be removed and replaced with gas. This process begins before birth as active sodium transport across the pulmonary epithelium drives liquid from the lung lumen into the interstitium with subsequent absorption into the vasculature. Increased levels of circulating catecholamines, vasopressin, prolactin, and glucocorticoids enhance lung fluid adsorption and trigger the change in lung epithelia from chloride secretion to sodium reabsorption. **Functional residual capacity (FRC)** must be established and maintained to develop a ventilation-perfusion relationship that will provide optimal exchange of oxygen and carbon dioxide between alveoli and blood.

The First Breath

Initiation of the first breath is caused by a decline in arterial oxygen tension (PaO_2) and pH and a rise in arterial carbon dioxide partial tension ($PaCO_2$) as a result of interruption of the placental circulation, redistribution of cardiac output, decrease in body temperature, and various tactile and sensory inputs. The relative contributions of these stimuli to the onset of respiration are uncertain.

Although spontaneously breathing infants do not need to generate an opening pressure to create airflow, infants requiring **positive pressure ventilation (PPV)** at birth need an opening pressure of 13-32 cm H_2O and are more likely to establish FRC if they generate a spontaneous, negative pressure breath. Expiratory esophageal pressures associated with the 1st few spontaneous breaths in term newborns range from 45-90 cm H_2O. This high pressure, caused by expiration against a partially closed glottis, may aid in the establishment of FRC but would be difficult to mimic safely with artificial ventilation. The higher pressures needed to initiate respiration are required to overcome the opposing forces of surface tension (particularly in small airways) and the viscosity of liquid remaining in the airways, as well as to introduce about 50 mL/kg of air into the lungs, 20-30 mL/kg of which remains after the first breath to establish FRC. **Surfactant** lining the alveoli enhances the aeration of gas-free lungs by reducing surface tension, thereby lowering the pressure required to open alveoli. Air entry into the lungs displaces fluid, decreases hydrostatic pressure in the pulmonary vasculature, and increases pulmonary blood flow. The greater blood flow in turn increases the blood volume of the lung and the effective vascular surface area available for fluid uptake. The remaining fluid is removed by the pulmonary lymphatics, upper airway, mediastinum, and pleural space. Fluid removal may be impaired after cesarean birth or as a result of surfactant deficiency, endothelial cell damage, hypoalbuminemia, high pulmonary venous pressure, or neonatal sedation.

Compared with term infants, preterm infants have a very compliant chest wall and may be at a disadvantage in establishing FRC. Abnormalities in ventilation-perfusion ratio are greater and persist for longer periods in preterm infants and may lead to hypoxemia and hypercarbia as a result of atelectasis, intrapulmonary shunting, hypoventilation, and gas trapping. The smallest immature infants have the most profound disturbances as a consequence of **respiratory distress syndrome (RDS)** . However, even in healthy term infants, oxygenation is impaired immediately after birth, and oxygen saturation (SO_2) gradually increases and exceeds 90% only at about 5 min. In addition, because of the relatively high pulmonary arterial pressure present in the fetal lung, right-to-left shunting across the ductus arteriosus is common soon after birth. If pulse oximetry is performed soon after birth, the recommendation is to measure preductal SO_2 in the right upper extremity.

Breathing Patterns in Newborns

During sleep in the 1st few mo after birth, normal full-term infants (and more frequently preterm infants) may have episodes when regular breathing is interrupted by short pauses. This **periodic breathing** pattern is characterized by brief episodes of respiratory pauses lasting 5-10 sec, followed by a burst of rapid respirations at a rate of 50-60 breaths/min for 10-15 sec. The brief interruptions in respiration are not associated with change in color or heart rate. Periodic breathing is a normal characteristic of neonatal respiration and has no prognostic significance.

122.2

Apnea

Shawn K. Ahlfeld

Keywords

- apnea
- mixed apnea
- central apnea
- obstructive apnea
- apnea of prematurity
- nasal continuous positive airway pressure
- heated humidified high-flow nasal cannula
- methylxanthines
- caffeine
- gastroesophageal reflux
- home monitoring
- sudden infant death syndrome

Apnea is a prolonged cessation of respiration and must be distinguished from **periodic breathing** because apnea is often associated with serious illness. Although there is no universal agreement, apnea is usually defined as cessation of breathing for a period of ≥20 sec, or a period <20 sec that is associated with a change in tone, pallor, cyanosis, or bradycardia (<80-100 beats/min). Based on the absence of respiratory effort and/or airflow, apnea can be obstructive, central, or mixed. **Obstructive apnea** (pharyngeal instability, neck flexion) is characterized by absence of airflow but persistent chest wall motion. Pharyngeal collapse may follow the negative airway pressures generated during inspiration, or it may result from incoordination of the tongue and other upper airway muscles involved in maintaining airway patency. **Central apnea,** which is caused by decreased central nervous system (CNS) stimuli to respiratory muscles, results in both airflow and chest wall motion being absent. Gestational age is the most important determinant of respiratory control, with the frequency of central apnea being inversely related to gestational age. The immaturity of the brainstem respiratory centers is manifest by an attenuated response to CO_2 and a paradoxical response to hypoxia that results in central apnea rather than hyperventilation. **Mixed apnea** is most often observed in **apnea of prematurity** (50–75% of cases), with obstructive apnea preceding central apnea. Short episodes of apnea are usually central, whereas prolonged ones are often mixed. Apnea depends on the sleep state; its frequency increases during active (rapid eye movement) sleep.

Although apnea is usually observed in preterm infants as a result of immature respiratory control or an associated illness, apnea in term infants is uncommon, often associated with serious pathology, and demands prompt diagnostic evaluation. Apnea accompanies many primary diseases that affect neonates (Table 122.1). These disorders produce apnea by direct depression of CNS control of respiration (hypoglycemia, meningitis, drugs, intracranial hemorrhage, seizures), disturbances in oxygen delivery (shock, sepsis, anemia), or ventilation defects (obstruction of the airway, pneumonia, muscle weakness).*The term neonate with apnea should receive continuous cardiorespiratory monitoring while performing an assessment for bacterial or viral sepsis/meningitis, intracranial hemorrhage, seizures, and airway instability.* Supportive care and close monitoring are essential while the underlying etiology is ascertained and appropriately treated.

Table 122.1

Potential Causes of Neonatal Apnea and Bradycardia

Central nervous system	Intraventricular hemorrhage, drugs, seizures, hypoxic injury, herniation, neuromuscular disorders, Leigh syndrome, brainstem infarction or anomalies (e.g., olivopontocerebellar atrophy), spinal cord injury after general anesthesia
Respiratory	Pneumonia, obstructive airway lesions, upper airway collapse, atelectasis, extreme prematurity, laryngeal reflex, phrenic nerve paralysis, pneumothorax, hypoxia
Infectious	Sepsis, meningitis (bacterial, fungal, viral), respiratory syncytial virus, pertussis
Gastrointestinal	Oral feeding, bowel movement, necrotizing enterocolitis, intestinal perforation
Metabolic	↓ Glucose, ↓ calcium, ↓/↑ sodium, ↑ ammonia, ↑ organic acids, ↑ ambient temperature,

	hypothermia
Cardiovascular	Hypotension, hypertension, heart failure, anemia, hypovolemia, vagal tone
Other	Immaturity of respiratory center, sleep state Sudden unexpected postnatal collapse

Apnea of Prematurity

Apnea of prematurity results from immature respiratory control, most frequently occurs in infants <34 wk of gestational age (GA), and occurs in the absence of identifiable predisposing diseases. The incidence of idiopathic apnea of prematurity varies inversely with GA. Apnea of prematurity is almost universal in infants born at <28 wk GA, and the incidence rapidly decreases from 85% of infants <30 wk GA to 20% of infants <34 wk GA. The onset of apnea of prematurity can be during the initial days to weeks of age but is often delayed if there is RDS or other causes of respiratory distress. In premature infants without respiratory disease, apneic episodes can occur throughout the 1st 7 postnatal days with equal frequency.

Apnea in preterm infants is defined as cessation of breathing for ≥20 sec or for any duration if accompanied by cyanosis and bradycardia (<80-100 beats/min). The incidence of associated bradycardia increases with the length of the preceding apnea and correlates with the severity of hypoxia. Short apnea episodes (10 sec) are rarely associated with bradycardia, whereas longer episodes (>20 sec) have a higher incidence of bradycardia. **Bradycardia** follows the apnea by 1-2 sec in >95% of cases and is most often sinus, but on occasion it can be nodal. Vagal responses and rarely heart block are causes of bradycardia *without* apnea. Short, self-resolving oxygen desaturation episodes noted with continuous monitoring are normal in neonates, and treatment is not necessary.

Preterm infants born at <35 wk GA are at risk for apnea of prematurity and therefore should receive cardiorespiratory monitoring. Apnea that occurs in the absence of other clinical signs of illness in the 1st 2 wk in a preterm infant is likely apnea of prematurity, and therefore additional evaluation for other etiologies is often unwarranted. However, the onset of apnea in a previously well preterm neonate after the 2nd wk of life (or, as previously, in a term infant at any time) is a critical event that may be associated with serious underlying pathology. Prompt investigation for medication side effects, metabolic derangements, structural CNS anomalies, intracranial hemorrhage, seizures, or sepsis/meningitis is warranted.

Treatment

Gentle tactile stimulation or provision of flow and/or supplemental oxygen by nasal cannula is often adequate therapy for mild and intermittent episodes. **Nasal continuous positive airway pressure** (nCPAP, 3-5 cm H_2 O) and **heated humidified high-flow nasal cannula** (HHHFNC, 1-4 L/min) are appropriate therapies for mixed or obstructive apnea. The efficacy of both nCPAP and HHHFNC is related to their ability to splint the upper airway to prevent airway obstruction. Both are used widely, but nCPAP may be preferred in extremely preterm infants because of its proven efficacy and safety.

Recurrent or persistent apnea of prematurity is effectively treated with **methylxanthines** . Methylxanthines increase central respiratory drive by lowering the threshold of response to hypercapnia as well as enhancing contractility of the diaphragm and preventing diaphragmatic fatigue. Caffeine and theophylline are similarly effective methylxanthines, but caffeine is preferred because of its longer half-life and lower potential for side effects (less tachycardia and feeding intolerance). In preterm infants, caffeine reduces the incidence and severity of apnea of prematurity, facilitates successful extubation from mechanical ventilation, reduces the rate of **bronchopulmonary dysplasia (BPD)** , and improves neurodevelopmental outcomes. Caffeine therapy can be safely administered orally (PO) or intravenously (IV) with an initial loading dose of 20 mg/kg of caffeine citrate followed 24 hr later by once-daily maintenance doses of 5 mg/kg (increased to 10 mg/kg daily as needed for persistent apnea). Because the therapeutic window is wide (therapeutic level: 8-20 µg/mL) and serious side effects associated with caffeine are rare, monitoring of serum drug concentrations are usually unnecessary. Monitoring is primarily through observation of vital signs (tachycardia) and clinical response. Higher doses of caffeine may be more effective without serious adverse events, but additional studies are needed to ensure safety. Retrospective cohort studies suggest that initiation of caffeine in the 1st 3 days of age in extremely preterm infants (<28 wk GA) may improve outcomes. However, it is reasonable to delay caffeine therapy until apnea occurs. Caffeine therapy is usually continued until an infant is free of clinically significant apnea or bradycardia for 5-7 days without positive pressure respiratory support, or at 34 wk postmenstrual age (PMA).

In an infant with significant anemia, transfusion of packed red blood cells (RBCs) increases blood O_2 -carrying capacity, improves tissue oxygenation, and is associated with a short-term reduction in apnea. However, a long-term benefit in regard to apnea appears unlikely. **Gastroesophageal reflux (GER)** is common in neonates, but despite being associated with apnea anecdotally, data *do not* support a causal relationship between GER and apneic events. In preterm infants, medications that inhibit gastric acid production have potentially harmful side effects (increased incidence of sepsis, necrotizing enterocolitis, death) and may actually increase the incidence of apnea and bradycardia. Therefore the routine use of medications that inhibit gastric acid synthesis or promote gastrointestinal motility to reduce the frequency of apnea in preterm infants should be discouraged.

Prognosis

In 92% of infants by 37 wk PMA and in 98% of infants by 40 wk PMA, apnea of prematurity resolves spontaneously. However, infants born well before 28 wk GA may experience apnea and bradycardic events until 44 wk PMA. Beyond 44 wk PMA, extreme events (apnea >30 sec and/or bradycardia <60 beats/min for >10 sec) are very rare. The period that an infant should be observed to ensure resolution of apnea and bradycardia is not defined and among institutions is highly variable. However, many experts would recommend that an infant demonstrate an event-free period of 5-7 days before discharge. Although the nature and severity of events should dictate the length of observation, sufficiently large retrospective cohort studies suggest that a 1-3 day (infants born at ≥30 wk GA), 9-10 day (27-28 wk GA), or 13-14 day (<26 wk GA) event-free period predicts resolution of apnea in up to 95% of infants successfully. Brief, isolated bradycardic episodes associated with oral feeding are common in preterm infants and are generally not considered significant during the event-free period. While not recommended routinely for preterm infants with apnea of prematurity, in *rare* cases an infant with persistent, prolonged apnea may be discharged with home cardiorespiratory monitoring. In the absence of significant events, home monitoring can be safely discontinued at 44 wk PMA. There is no evidence that home monitoring prevents death.

Despite its high frequency in preterm infants, the harm associated with apnea of prematurity is unknown. However, apnea of prematurity does not appear to alter an infant's prognosis unless it is severe, recurrent, and refractory to therapy. Prompt, effective therapy and careful monitoring are vital to avoid prolonged, severe hypoxia, which may increase the risk of death and neurodevelopmental impairment.

Apnea of Prematurity and Sudden Infant Death Syndrome

Although preterm infants are at higher risk for sudden infant death syndrome (SIDS), apnea of prematurity does not further increase that risk. The peak incidence of SIDS occurs earlier in infants born at 24-28 wk GA (47.1 wk PMA vs 53.5 wk PMA). The epidemiologic evidence that placing babies supine during sleep reduces the rate of SIDS deaths by >50% suggests that positioning, and not prematurity, primarily influences the incidence of SIDS. Supine positioning on a firm sleep surface separate from the parents' bed, promotion of breastfeeding, and pacifier use during sleep reduce the incidence of SIDS. Avoidance of cigarette smoke exposure and no parental use of alcohol or illicit drugs during pregnancy and after birth are also important in the prevention of SIDS.

Incidence

Respiratory distress syndrome (RDS) occurs primarily in premature infants; its incidence is inversely related to gestational age and birthweight. It occurs in 60–80% of infants <28 wk GA, in 15–30% of those between 32 and 36 wk GA, and rarely in those >37 wk GA. The risk for development of RDS increases with maternal diabetes, multiple births, cesarean delivery, precipitous delivery, asphyxia, cold stress, and a maternal history of previously affected infants. The risk of RDS is reduced in pregnancies with chronic or pregnancy-associated hypertension, maternal heroin use, prolonged rupture of membranes, and antenatal corticosteroid prophylaxis.

Etiology and Pathophysiology

Surfactant deficiency (decreased production and secretion) is the primary cause of RDS. In the absence of pulmonary surfactant, significantly increased alveolar surface tension leads to atelectasis, and the ability to attain an adequate FRC is impaired. As a consequence of progressive injury to epithelial and endothelial cells from atelectasis (atelectrauma), volutrauma, ischemic injury, and oxygen toxicity, effusion of proteinaceous material and cellular debris into the alveolar spaces (forming the classic *hyaline membranes*) further impairs oxygenation. Alveolar atelectasis, hyaline membrane formation, and interstitial edema make the lungs less compliant in RDS, so greater pressure is required to expand the alveoli and small airways. Additionally, compared with the mature infant, the highly compliant chest wall of the preterm infant offers less resistance to the natural tendency of the lungs to collapse. Thus, at end-expiration, the volume of the thorax and lungs tends to approach residual volume. Although surfactant is present in high concentrations in fetal lung homogenates by 20 wk of gestation, it does not reach the surface of the lungs until later. It appears in amniotic fluid between 28 and 32 wk. Mature levels of pulmonary surfactant are present usually after 35 wk of gestation.

The major constituents of surfactant are dipalmitoyl phosphatidylcholine (lecithin), phosphatidylglycerol, apoproteins (surfactant proteins SP-A, SP-B, SP-C, and SP-D), and cholesterol (Fig. 122.2). With advancing GA, increasing amounts of phospholipids are synthesized and stored in type II alveolar cells (Fig. 122.3). These surface-active agents are released into the alveoli, where they reduce surface tension and help maintain alveolar stability at end-expiration. Synthesis of surfactant depends in part on normal pH, temperature, and perfusion. Asphyxia, hypoxemia, and pulmonary ischemia, particularly in association with hypovolemia, hypotension, and cold stress, may suppress surfactant synthesis. The epithelial lining of the lungs may also be injured by high O_2 concentrations and mechanical ventilation, thereby further reducing secretion of surfactant.

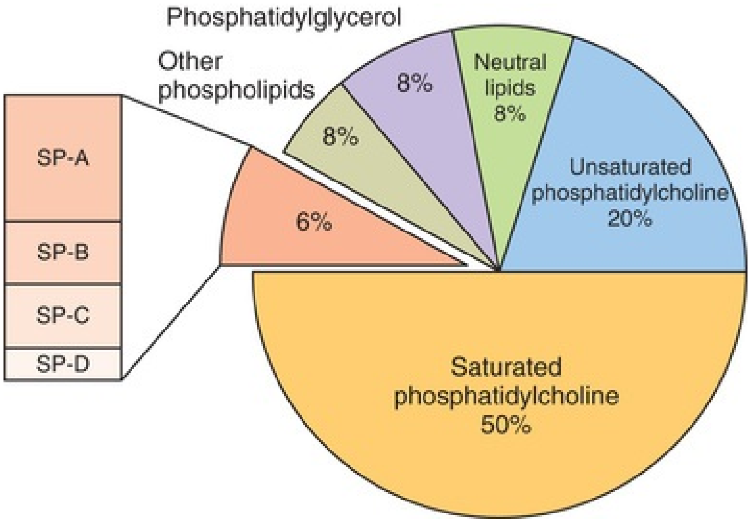

FIG. 122.2 **Composition of surfactant. SP-A, Surfactant-associated protein A; SP-B, surfactant-associated protein B; SP-C, surfactant-associated protein C; SP-D, surfactant-associated protein D. (From Jobe AH, Ikegami M: Biology of surfactant, *Clin Perinatol* 28:655–669, 2001.)**

Atelectasis results in perfused but not ventilated alveoli, causing hypoxia. Decreased lung compliance, small tidal volumes, increased physiologic dead space, and insufficient alveolar ventilation eventually result in hypercapnia. The combination of hypercapnia, hypoxia, and acidosis produces pulmonary arterial vasoconstriction with increased right-to-left shunting through the foramen ovale and ductus arteriosus and within the lung itself. Progressive injury to epithelial and endothelial cells and formation of hyaline membranes further impairs oxygenation, leading to a vicious cycle of diminished surfactant production, worsening atelectasis, lung injury, and severe hypoxia (Fig. 122.4).

Reprinted by permission of John Wiley and Sons, Inc.)**

Clinical Manifestations

Signs of RDS usually appear within minutes of birth, although they may not be recognized for several hours in larger premature infants, until rapid, shallow respirations become more obvious. A later onset of tachypnea should suggest other conditions. Some patients require resuscitation at birth because of intrapartum asphyxia or initial severe respiratory distress (especially with birthweight <1,000 g). Characteristically, tachypnea, prominent (often audible) expiratory grunting, intercostal and subcostal retractions, nasal flaring, and cyanosis are noted. Breath sounds may be normal or diminished with a harsh tubular quality, and on deep inspiration, fine crackles may be heard. The natural course of untreated RDS is characterized by progressive worsening of cyanosis and dyspnea. If the condition is inadequately treated, blood pressure may fall; cyanosis and pallor increase, and grunting decreases or disappears, as the condition worsens. *Apnea and irregular respirations are ominous signs requiring immediate intervention.* Untreated patients may also have a mixed respiratory-metabolic acidosis, edema, ileus, and oliguria. Respiratory failure may occur in infants with rapid progression of the disease. In most cases the signs reach a peak within 3 days, after which improvement is gradual. Improvement is often heralded by spontaneous diuresis and improved blood gas values at lower inspired O_2 levels and/or lower ventilator support. Death can result from severe impairment of gas exchange, alveolar air leaks (pulmonary interstitial emphysema, pneumothorax), pulmonary hemorrhage, or intraventricular hemorrhage (IVH).

Diagnosis

The clinical course, chest x-ray findings, and blood gas values help establish the clinical diagnosis. On chest radiograph, the lungs may have a characteristic but not pathognomonic appearance that includes low lung volumes, a diffuse, fine reticular granularity of the parenchyma (ground-glass appearance), and air bronchograms (Fig. 122.5). The initial x-ray appearance is occasionally normal, with the typical pattern developing during the 1st day. Considerable variation in radiographic findings may be seen, especially in infants who have already received treatment with surfactant replacement and/or positive pressure respiratory support; this variation often results in poor correlation between radiographic findings and the clinical course. Blood gas findings are characterized initially by hypoxemia and later by progressive hypoxemia, hypercapnia, and variable metabolic acidosis.

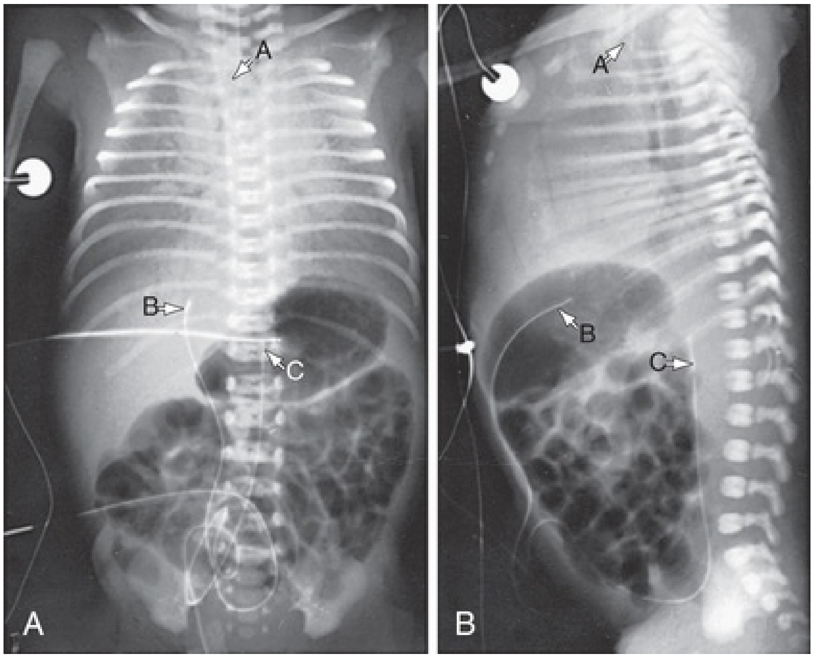

FIG. 122.5 Infant with respiratory distress syndrome. Note the granular lungs, air bronchogram, and air-filled esophagus. A, Anteroposterior, and B, lateral, radiographs are needed to distinguish the umbilical artery from the vein catheter and to determine the appropriate level of insertion. The lateral view clearly shows that the catheter has been inserted into an umbilical vein and is lying in the portal system of the liver. *A* indicates endotracheal tube; *B* indicates the umbilical venous catheter at the junction of the umbilical vein, ductus venosus, and portal vein; *C* indicates the umbilical artery catheter passed up the aorta to T12. (Courtesy of Walter E. Berdon, Babies Hospital, New York City.)

In the differential diagnosis, early-onset sepsis may be indistinguishable from RDS. In neonates with pneumonia, the chest radiograph may be identical to that for RDS. Clinical factors such as maternal group B streptococcal colonization with inadequate intrapartum antibiotic prophylaxis, maternal fever (>38.6°C) or chorioamnionitis, or prolonged rupture of membranes (>12 hr) are associated with an increased risk of early-onset sepsis. Although complete blood counts are neither sensitive nor specific in the diagnosis of early-onset sepsis, the presence of marked neutropenia has been associated with increased risk. Cyanotic congenital heart disease (in particular, total anomalous pulmonary venous return) can also mimic RDS both clinically and radiographically. Echocardiography with color-flow imaging should be performed in infants who show no response to surfactant replacement, to rule out cyanotic congenital heart disease as well as ascertain patency of the ductus arteriosus and assess pulmonary vascular resistance (PVR). Persistent pulmonary hypertension, aspiration (meconium, amniotic fluid) syndromes, spontaneous pneumothorax, pleural effusions, and congenital anomalies (pulmonary congenital airway malformations, pulmonary lymphangiectasia, diaphragmatic hernia, lobar emphysema) must be considered in patients with an atypical clinical course but can generally be differentiated from RDS through radiographic and other evaluations. Transient tachypnea may be distinguished by its shorter and milder clinical course and is characterized by low or no need for O_2 supplementation.

Although rare, genetic disorders may contribute to respiratory distress. Abnormalities in surfactant protein B and C genes as well as a gene responsible for transporting surfactant across membranes, ABC transporter 3 (*ABCA3*), are associated with severe and often lethal familial respiratory disease. **Congenital alveolar proteinosis** (congenital surfactant protein B deficiency) is a rare familial disease that manifests as severe and lethal RDS in predominantly term and near-term infants (see Chapter 434). In atypical cases of RDS, a lung profile (lecithin:sphingomyelin ratio and phosphatidylglycerol determination) performed on a tracheal aspirate can be helpful in establishing a diagnosis of surfactant deficiency. Other familial causes of neonatal respiratory distress (not RDS) include mucopolysaccharidosis, acinar dysplasia, pulmonary lymphangiectasia, and alveolocapillary dysplasia.

Prevention

Avoidance of unnecessary or poorly timed early (<39 wk GA) cesarean delivery or induction of labor, appropriate management of high-risk pregnancy and labor (including administration of antenatal corticosteroids), and prediction of pulmonary immaturity with possible in utero acceleration of maturation (see Chapter 119) are important preventive strategies. Antenatal and intrapartum fetal monitoring may decrease the risk of fetal asphyxia; asphyxia is associated with an increased incidence and severity of RDS.

Administration of antenatal corticosteroids to women before 37 wk gestation significantly reduces the incidence and mortality of RDS as well as overall neonatal mortality. Antenatal steroids also reduce (1) overall mortality, (2) admission to the neonatal intensive care unit (NICU) and need for/duration of ventilatory support, and (3) incidence of severe IVH, necrotizing enterocolitis (NEC), and neurodevelopmental impairment. Postnatal growth is not adversely affected. Antenatal corticosteroids do not increase the risk of maternal death, chorioamnionitis, or puerperal sepsis. **Betamethasone** and **dexamethasone** have both been used antenatally. Betamethasone may reduce neonatal death to a greater extent than dexamethasone.

Although classically, antenatal corticosteroids were reserved for preterm birth before 34 wk gestation, the administration of betamethasone before late preterm birth (34^{+0} to 36^{+6} wk gestation) significantly reduces the need for respiratory support and the incidence of severe respiratory complications. Therefore the American College of Obstetricians and Gynecologists (ACOG) recommends that for all women between 24 and 36 wk gestation who present in preterm labor and are likely to deliver a fetus within 1 wk, antenatal corticosteroid administration should be considered.

Treatment

The basic defect requiring treatment in RDS is inadequate pulmonary O_2 -CO_2 exchange. Basic supportive care (thermoregulatory, circulatory, fluid, electrolyte, and respiratory) is essential while FRC is established and maintained. Careful and frequent monitoring of heart and respiratory rates, SaO_2 , PaO_2 , $PaCO_2$, pH electrolytes, glucose, hematocrit, blood pressure, and temperature are essential. Arterial catheterization is frequently necessary. Because most cases of RDS are self-limited, the goal of treatment is to minimize abnormal physiologic variations and superimposed iatrogenic problems. Treatment of infants with RDS is best carried out in the NICU.

Periodic monitoring of PaO_2 , $PaCO_2$, and pH is an important part of the management and is used to provide supportive care; if assisted ventilation is being used, such monitoring is essential. Oxygenation (SO_2) should be assessed by continuous pulse oximetry. Capillary blood samples are of limited value for determining PO_2 but may be useful for PCO_2 and pH monitoring. Monitoring of blood gas parameters and mean arterial blood pressure through an umbilical or peripheral arterial catheter is useful in managing the shock-like state that may occur during the initial hours in premature infants who have been asphyxiated or have severe RDS (see Fig. 121.3). The position of a radiopaque umbilical catheter should be checked radiographically after insertion (see Fig. 122.5). The tip of an umbilical artery catheter should lie at L3-L5 just above the bifurcation of the aorta or at T6-T10. The placement and supervision should be carried out by skilled and experienced personnel. Catheters should be removed as soon as patients no longer have any indication for their continued use—usually when an infant is stable and the fraction of inspired oxygen (FIO_2) is <40%.

Nasal Continuous Positive Airway Pressure

Warm, humidified oxygen should be provided at a concentration sufficient to keep PaO_2 between 50 and 70 mm Hg (91–95% SaO_2) to maintain normal tissue oxygenation while minimizing the risk of O_2 toxicity. If there is significant respiratory distress (severe retractions and expiratory grunting) or if SaO_2 cannot be kept >90% at FIO_2 of $\geq$40–70%, applying nCPAP at 5-10 cm H_2O is indicated and usually produces a rapid improvement in oxygenation. Nasal CPAP reduces collapse of surfactant-deficient alveoli and improves both FRC and ventilation-perfusion matching. *Early use of nCPAP for stabilization of at-risk preterm infants beginning early (in the delivery room) reduces the need for mechanical ventilation.*

Recognizing the benefits of surfactant replacement therapy, in addition to the potential protective effects of prophylactic nCPAP, some experts recommend intubation for prophylactic or early rescue surfactant replacement therapy, followed by extubation back to nCPAP immediately once the infant is stable (usually within minutes to <1 hr). The aforementioned method is commonly referred to as **intubate surfactant and extubate** (INSURE). A variation of the INSURE method has evolved known as MIST (**minimally invasive surfactant therapy**) or LISA (**less invasive surfactant administration**), in which a small feeding tube, rather than an endotracheal tube (ETT), is used to deliver intratracheal surfactant to a spontaneously breathing infant on nCPAP. The combination of early rescue surfactant by the INSURE, MIST, or LISA method with nCPAP has been associated with the reduced need for mechanical ventilation, and emerging evidence suggests modest benefits in terms of preventing BPD. The amount of nCPAP required usually decreases after approximately 72 hr of age, and most infants can be weaned from nCPAP shortly thereafter. *Assisted ventilation and surfactant are indicated for infants with RDS who cannot keep oxygen saturation >90% while breathing 40–70% oxygen and receiving nCPAP.*

In an effort to minimize ventilator-associated lung injury and prevent long-term pulmonary complications, the use of nCPAP as the initial respiratory support for extremely preterm infants is preferred. The decreased need for ventilator support with the use of nCPAP may allow lung inflation to be maintained while preventing lung injury. Early nCPAP is beneficial compared to intubation and prophylactic surfactant, because avoidance of mechanical ventilation is associated with a reduction in death and/or BPD. Infants at the extremes of GA (<24 wk) and those that were not exposed to antenatal corticosteroids may still benefit from intubation and surfactant prophylaxis.

Mechanical Ventilation

Infants with respiratory failure or persistent apnea require assisted mechanical ventilation. Strict definitions for respiratory failure in extremely preterm infants with RDS are not agreed on universally, but reasonable measures of respiratory failure are (1) arterial blood pH <7.20, (2) $Pa\text{CO}_2$ ≥60 mm Hg, (3) $Sa\text{O}_2$ <90% at O_2 concentration of 40–70% and nCPAP of 5-10 cm H_2O, and (4) persistent or severe apnea. The goal of mechanical ventilation is to improve oxygenation and ventilation without causing pulmonary injury or oxygen toxicity. Acceptable ranges of ABG values vary significantly among institutions but generally range from $Pa\text{O}_2$ 50-70 mm Hg, $Pa\text{CO}_2$ 45-65 mm Hg (and higher after the 1st few day when risk of IVH is less), and pH 7.20-7.35. During mechanical ventilation, oxygenation is improved by increasing either $F\text{IO}_2$ or the mean airway pressure. The mean airway pressure can be increased by raising the peak inspiratory pressure (PIP), inspiratory time, ventilator rate, or positive end-expiratory pressure (PEEP). Adjustment in pressure is usually most effective. However, excessive PEEP may impede venous return, thereby reducing cardiac output and O_2 delivery. Assisted ventilation for infants with RDS should always include appropriate PEEP (see Chapter 89.1). PEEP levels of 4-6 cm H_2O are usually safe and effective. CO_2 elimination is determined by the minute ventilation, which is a product of the tidal volume (dependent on the inspiratory time and PIP) and ventilator rate. Because of the homogeneous nature of the lung pathology associated with RDS, a high rate (≥60/min), low tidal volume (4-6 mL/kg) strategy is generally effective. Meta-analyses comparing high (>60 breaths/min) and low (usually 30-40 breaths/min) rates (and presumed low vs high tidal volumes, respectively) revealed that the high ventilatory rate strategy led to fewer air leaks and a trend for increased survival. With use of high ventilatory rates, sufficient expiratory time should be allowed to avoid air-trapping and inadvertent PEEP.

Modes of Mechanical Ventilation

Synchronized intermittent mechanical ventilation (SIMV) delivered by time-cycled, pressure-limited, continuous flow ventilators is a common method of conventional ventilation for newborns. With pressure-limited SIMV, a set PIP is delivered in synchrony with the patient's own breaths for a specified rate per minute. For breaths above the set rate, pressure support breaths (8-10 cm H_2O above PEEP) are provided to help overcome the resistance associated with spontaneous breathing through the ETT. In *pressure-limited ventilation* the delivered tidal volume is directly proportional to the respiratory compliance. Rapid changes in compliance occur with surfactant replacement therapy, requiring careful attention to tidal volumes and appropriate adjustments in PIP. Advances in ventilator technology have allowed the delivery of very small (<10 mL) tidal volume breaths consistently. In *volume-targeted ventilation* a specific tidal volume is set, and the PIP required to deliver it varies inversely with the respiratory compliance. Other modes of volume-targeted ventilation calculate the lowest effective PIP to deliver the set tidal volume. Evidence suggests that volume-targeted ventilation results in fewer air leaks and may improve survival without BPD.

High-frequency ventilation (HFV) achieves desired alveolar ventilation by using smaller tidal volumes and higher rates (300-1,200 breaths/min or 5-20 Hz). HFV may improve elimination of CO_2 and improve oxygenation in patients who show no response to conventional ventilators, as well as those who have severe RDS, interstitial emphysema, recurrent pneumothoraces, or meconium aspiration pneumonia. **High-frequency oscillatory ventilation** (HFOV) and **high-frequency jet ventilation** (HFJV) are the most frequently used methods. HFOV may reduce BPD but the effect size is likely small. In severe respiratory failure unresponsive to conventional mechanical ventilation, HFOV strategies that promote lung recruitment, combined with surfactant therapy, may improve gas exchange. HFJV is particularly useful to facilitate resolution of air leaks. Elective use of either HFV method, in comparison with conventional ventilation, generally does not offer advantages when used as the initial ventilation strategy to treat infants with RDS.

Permissive Hypercapnia and Avoidance of Hyperoxia

Permissive hypercapnia is a strategy for management of patients receiving ventilatory support in whom priority is given to limiting ventilator-associated lung injury by tolerating relatively high levels of $Paco_2$ (>60-70 mm Hg). Permissive hypercapnia can be implemented during nCPAP and mechanical ventilation but has not been shown to significantly impact outcomes. **Hyperoxia**

may also contribute to lung injury in preterm infants. However, a lower target range of oxygenation (85–89%) compared with a higher range (91–95%) increases mortality and does not alter rates of BPD, BPD/death, blindness, or neurodevelopmental impairment. *Therefore the currently recommended range of oxygen saturation targets is 91–95%.*

Discontinuation of Mechanical Ventilation

Strategies for weaning infants from ventilators vary widely and are influenced by lung mechanics as well as the availability of ventilatory modes. Extubation to nCPAP prevents postextubation atelectasis and reduces the need for reintubation. Synchronized **nasal intermittent positive pressure ventilation** (NIPPV) also decreases the need for reintubation in premature infants, but ventilators capable of synchronization with nasal ventilation are not widely available. HHHFNC (1-8 L/min) oxygen is typically used to support term and near-term infants following extubation. It is not clear whether nCPAP, NIPPV, or HHHFNC is more efficacious for promoting normal lung development and preventing BPD, but there is more evidence associated with nCPAP in extremely preterm infants. Preloading with methylxanthines enhances the success of extubation.

Surfactant Replacement Therapy

Surfactant deficiency is the primary pathophysiology of RDS. Immediate effects of surfactant replacement therapy include improved alveolar-arterial oxygen gradients, reduced ventilatory support, increased pulmonary compliance, and improved chest radiograph appearance. In the past, intratracheal surfactant replacement for symptomatic premature infants immediately after birth (prophylactic) or during the 1st few hr of life (early rescue) showed reduced air leak and mortality from RDS. However, substantial evidence supports the feasibility and efficacy of prophylactic nCPAP as the *primary* means of respiratory support for preterm infants with RDS. CPAP started at birth is as effective as prophylactic or early surfactant and is associated with a reduction in BPD. *Prophylactic nCPAP is therefore the approach of choice for the delivery room management of a preterm neonate at risk for RDS.*

In neonates with RDS who fail nCPAP and require intubation and mechanical ventilation, treatment with endotracheal surfactant should be initiated immediately to avoid lung injury. Repeated dosing is given every 6-12 hr for a total of 2-4 doses, depending on the preparation. Exogenous surfactant should be given by a physician who is qualified in neonatal resuscitation and respiratory management. Additional required onsite staff support includes nurses and respiratory therapists experienced in the ventilatory management of preterm infants. Appropriate monitoring equipment (radiology, blood gas laboratory, pulse oximetry) must also be available. Complications of surfactant replacement therapy include transient hypoxia, hypercapnia, bradycardia and hypotension, blockage of ETT, and pulmonary hemorrhage.

A number of surfactant preparations are available, including synthetic surfactants and natural surfactants derived from animal sources. There do not appear to be significant, consistent benefits to one preparation over another. Infants requiring ventilator support after 1 wk of age may experience transient episodes of surfactant dysfunction temporally associated with episodes of infection and respiratory deterioration. Surfactant treatment may be beneficial in these infants.

Other Pharmacologic Therapies

There are no pharmacologic therapies superior or equal to the efficacy of maintaining FRC (through noninvasive respiratory support and mechanical ventilation when necessary) and providing surfactant replacement therapy in the treatment of RDS. Systemic corticosteroids (predominantly dexamethasone), although effective in improving respiratory mechanics and preventing BPD and death, are associated with increased risk of cerebral palsy and neurodevelopmental impairment when used indiscriminately. Thus, routine use of systemic corticosteroids for the prevention or treatment of BPD is not recommended by the Consensus Group of the American Academy of Pediatrics and the Canadian Pediatric Society. Early (1st 10 days of life), low-dose administration (1 mg/kg/day hydrocortisone twice daily for 7 days; 0.5 mg/kg/day for 3 days) may reduce the risk of BPD in neonates <28 wk GA. In general, administration of inhaled corticosteroids to ventilated preterm infants during the 1st 2 wk after birth has not proved to be consistently advantageous.

Inhaled nitric oxide (iNO) has been evaluated in preterm infants following the observation of its effectiveness in term and near-term infants with hypoxemic respiratory failure. Although iNO improves oxygenation in term and near-term infants with hypoxic respiratory failure or persistent pulmonary hypertension of the neonate, trials in preterm infants have not shown significant benefit. The most current data do not support the routine administration of iNO in preterm infants with hypoxemic respiratory failure.

Hypotension and low flow in the superior vena cava have been associated with higher rates of CNS morbidity and mortality and should be treated with cautious administration of crystalloid (if volume depletion due to hemorrhage or excessive insensible fluid losses is suspected) and early use of vasopressors. Dopamine is more effective in raising blood pressure than dobutamine. Hypotension that is refractory to vasopressor therapy, especially in neonates <1,000 g, may be caused by transient adrenal insufficiency. Administration of intravenous hydrocortisone at 1-2 mg/kg/dose every 6-12 hr may improve blood pressure and allow weaning of vasopressors.

Because of the difficulty in distinguishing group B streptococcal or other bacterial infections from RDS, empirical antibiotic therapy may be indicated until the results of blood cultures are available. Penicillin or ampicillin with an aminoglycoside is suggested, although the choice of antibiotics should be based on the recent pattern of bacterial sensitivity in the hospital where the infant is being treated (see Chapter 129).

Complications

Early provision of intensive observation and care of high-risk newborn infants can significantly reduce the morbidity and mortality associated with RDS and other acute neonatal illnesses. Antenatal corticosteroids, postnatal surfactant use, and improved modes of ventilation have resulted in low mortality from RDS (approximately 10%). Mortality increases with decreasing gestational age. Optimal results depend on the availability of experienced and skilled personnel, care in specially designed and organized regional hospital units, proper equipment, and lack of complications such as severe asphyxia, intracranial hemorrhage, or irremediable congenital malformation.

The most serious complications of endotracheal intubation are **pulmonary air leaks** , asphyxia from obstruction or dislodgment of the tube, bradycardia during intubation or suctioning, and the subsequent development of **subglottic stenosis** . Other complications include bleeding from trauma during intubation, posterior pharyngeal pseudodiverticula, need for tracheostomy, ulceration of the nares caused by pressure from the tube, permanent narrowing of the nostril as a result of tissue damage and scarring from irritation or infection around the tube, erosion of the palate, avulsion of a vocal cord, laryngeal ulcer, papilloma of a vocal cord, and persistent hoarseness, stridor, or edema of the larynx.

Measures to reduce the incidence of these complications include skillful intubation, adequate securing of the tube, use of polyvinyl ETTs, use of the smallest tube that will provide effective ventilation in order to reduce local pressure necrosis and ischemia, avoidance of frequent changes and motion of the tube in situ, avoidance of too frequent or too vigorous suctioning, and prevention of infection through meticulous cleanliness and frequent sterilization of all apparatus attached to or passed through the tube. The personnel inserting and caring for the ETT should be experienced and skilled in such care.

Extrapulmonary air leaks (pneumothorax, pneumomediastinum, pulmonary interstitial emphysema) are observed in 3–9% of extremely preterm infants with RDS (see Chapter 122.12). PPV with excessive inspiratory pressures (and therefore excessive tidal volumes), either during resuscitation at delivery or in the initial hours of mechanical ventilation, is a common risk factor, but air leaks can also occur in infants breathing spontaneously. Although the risk of air leak was increased in infants receiving a higher level of nCPAP (up to 8 cm H_2O) in the CPAP or Intubation at Birth (COIN) trial, subsequent trials have not demonstrated a similar effect.

Risks associated with **umbilical arterial catheterization** include vascular embolization, thrombosis, spasm, and vascular perforation; ischemic or chemical necrosis of abdominal viscera; infection; accidental hemorrhage; hypertension; and impairment of circulation to a leg with subsequent gangrene. Aortography has demonstrated that clots form in or about the tips of 95% of catheters placed in an umbilical artery. Aortic ultrasonography can also be used to investigate for the presence of thrombosis. **Renovascular hypertension** may occur days to weeks after umbilical arterial catheterization in a small proportion of neonates. Transient blanching of the leg may occur during catheterization of the umbilical artery. It is usually caused by reflex arterial spasm, the incidence of which is lessened by using the smallest available catheter, particularly in very small infants. The catheter should be removed immediately; catheterization of the other artery may then be attempted. **Umbilical vein catheterization** is associated with many of the same risks as umbilical artery catheterization. Additional risks are cardiac perforation and pericardial tamponade; improperly placed catheters in the portal vein can lead to thrombosis. The risk of a serious clinical complication resulting from umbilical catheterization is probably 2–5%.

Incidence

Bronchopulmonary dysplasia (**BPD** , also known as **chronic lung disease of prematurity**) is a clinical pulmonary syndrome that develops in the majority of extremely preterm infants and is defined by a prolonged need for respiratory support and supplemental oxygen. Almost 60% of infants born at ≤28 wk gestation will develop BPD, and the incidence of BPD increases inversely with gestational age. For infants born at the extreme of viability (22-24 wk), essentially 100% will develop BPD, the majority of whom will have moderate to severe disease. As neonatal care has improved and use of antenatal corticosteroids has become the standard of care, survival of infants born at the extreme of viability has improved, and BPD is encountered with increased prevalence. In the United States, an additional 10,000-15,000 new cases occur annually. Despite decades of experience, the incidence of BPD remains largely unchanged.

Etiology and Pathophysiology

BPD develops following preterm birth and the necessary life-supporting interventions (particularly mechanical ventilation and supplemental oxygen) that cause neonatal lung injury. As the limit of viability has been lowered by advances in neonatal care, the clinical syndrome associated with BPD has evolved. The clinical, radiographic, and lung histology of classic BPD described in 1967, before widespread use of antenatal corticosteroids and postnatal surfactant, was that of a disease of preterm infants who were more mature. During that era, infants born ≤30-32 wk gestation rarely survived. Infants who developed BPD demonstrated classic RDS initially, but the injurious mechanical ventilation and excessive supplemental oxygen required to support them resulted in a progressive, severe fibroproliferative lung disease. Improvements in respiratory care, as well as the introduction of surfactant and antenatal steroids, have allowed for gentle respiratory support strategies, and the need for excessive ventilator support and high percentages of inspired supplemental oxygen has decreased.

Despite a reduction in the fibroproliferative disease described previously, infants born in the modern era of neonatal care continued to require supplemental oxygen for prolonged periods. The *new* BPD is a disease primarily of infants with birthweight <1,000 g who were born at <28 wk gestation, some of whom have little or no lung disease at birth but over the 1st weeks of age experience progressive respiratory failure. Infants with the new BPD are born at a more immature stage of distal lung development, and lung histology demonstrates variable saccular wall fibrosis, minimal airway disease, abnormal pulmonary microvasculature development, and alveolar simplification. Although the etiology remains incompletely understood, the histopathology of BPD indicates interference with normal alveolar septation and microvascular maturation.

The pathogenesis of BPD is likely multifactorial, but pulmonary inflammation and lung injury are consistently observed. Alveolar collapse (**atelectrauma**) as a consequence of surfactant deficiency, together with ventilator-induced phasic overdistention of the lung (**volutrauma**), promotes lung inflammation and injury. Supplemental oxygen produces free radicals that cannot be metabolized by the immature antioxidant systems of very-low-birthweight (VLBW) neonates and further contributes to the injury. Pulmonary inflammation evidenced by infiltration of neutrophils and macrophages in alveolar fluid, as well as a host of proinflammatory cytokines, contributes to the progression of lung injury. Pre- and postnatal infection, excessive pulmonary blood flow via the patent ductus arteriosus (PDA), excessive administration of intravenous fluid, and pre- and postnatal growth failure are also significantly associated with the development of BPD. While the mechanisms are unclear, all likely promote lung injury by necessitating increased or prolonged respiratory support or interfering with lung repair. Regardless, the result is an interference with normal development of the alveolar-capillary unit and interference with normal gas exchange.

Clinical Manifestations

Over the 1st several wk of age, infants developing BPD demonstrate persistent, often progressive respiratory distress and the need for respiratory support and supplemental oxygen. In extremely-low-birthweight (ELBW) infants at risk for BPD, the need for supplemental oxygen over the 1st 2 wk of age follows 1 of 3 distinct patterns. Infants that follow the natural course of RDS, and by the 3-4 days of age require minimal (FIO_2 <0.25) supplemental oxygen, have a low (<20%) risk of developing BPD. Infants who initially have a low O_2 requirement (FIO_2 <0.25) during the 1st wk, but then experience early pulmonary deterioration and increased O_2 requirement (FIO_2 >0.25) during the 2nd wk, have a modest risk (approximately 50%) of developing BPD. Infants that have an early, persistently high (FIO_2 >0.25) need for supplemental oxygen have a significantly high (70%) risk of developing BPD.

Respiratory distress, commonly characterized by tachypnea and retractions, persists or worsens and is associated with hypercapnia, hypoxia, and oxygen dependence. The chest radiograph evolves from that of RDS to relative hyperinflation and fine, diffuse interstitial opacities. Wandering atelectasis is common. In the most severe cases, usually associated with prolonged mechanical ventilation and chronically high supplemental oxygen needs, frank cystic changes and/or pneumatoceles are observed (Fig. 122.6). Infants with severe BPD often demonstrate airway obstruction. Excessive airway mucus and edema, airway instability caused by acquired tracheobronchomalacia, and bronchospasm are proposed etiologies. Acute airway obstruction is manifest clinically by abrupt hypoxemia and bradycardia and is often referred to as *BPD spells* . Acute, intermittent right-to-left intracardiac or intrapulmonary shunting caused by abrupt elevations in pulmonary artery pressure may also contribute. Spells are notoriously difficult to control, but occasionally will respond to bronchodilators and sedation acutely.

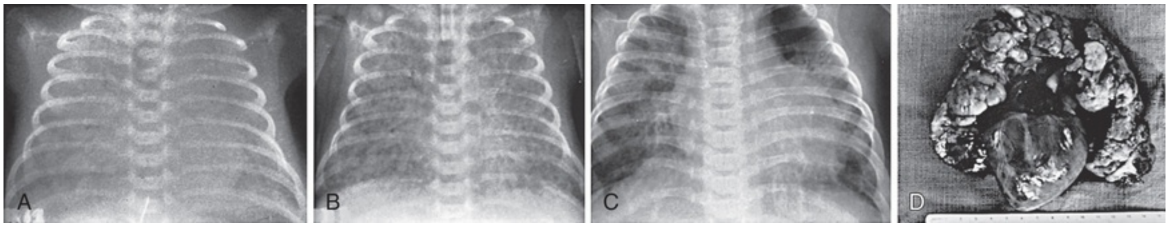

FIG. 122.6 **Pulmonary changes in infants treated with prolonged, intermittent positive pressure breathing with air containing 80–100% oxygen in the immediate postnatal period for the clinical syndrome of hyaline membrane disease. A, A 5 day old infant with nearly complete opacification of the lungs. B, A 13 day old infant with "bubbly lungs" simulating the radiographic appearance of the Wilson-Mikity syndrome. C, A 7 mo old infant with irregular, dense strands in both lungs, hyperinflation, and cardiomegaly suggestive of chronic lung disease. D, Large right ventricle and a cobbly, irregular aerated lung of an infant who died at 11 mo of age. This infant also had a patent ductus arteriosus. (From Northway WH Jr, Rosan RC, Porter DY: Pulmonary disease following respiratory therapy of hyaline-membrane disease, *N Engl J Med* 276:357–368, 1967.)**

A common, increasingly recognized complication of BPD is **pulmonary hypertension** . Prospective surveillance indicates that in approximately 15% of all infants born at <1,000 g and <28 wk GA, echocardiographic signs of pulmonary hypertension will develop. Prenatal growth restriction, prolonged duration of mechanical ventilation and supplemental oxygen, and increasing severity of BPD are all associated with an increased risk. Pulmonary hypertension has been reported in as many as 40% of infants with the most severe BPD and can progress to right-sided heart failure. Consistently, pulmonary hypertension complicating BPD has been associated with increased mortality.

Diagnosis

BPD is diagnosed when a preterm infant requires supplemental oxygen for the 1st 28 postnatal days, and it is further classified at 36 wk PMA according to the degree of O_2 supplementation (Table 122.2). Neonates receiving positive pressure support or ≥30% supplemental O_2 at 36 wk PMA or at discharge (whichever occurs first) are diagnosed as having **severe** BPD; those requiring 22–29% supplemental O_2 have **moderate** BPD; and those who previously required O_2 supplementation for at least 28 days but are currently breathing room air have **mild** BPD. Infants receiving <30% supplemental O_2 should undergo a stepwise 2% reduction in supplemental O_2 to room air while under continuous observation and with So_2 monitoring to determine whether they can be weaned off oxygen (physiologic definition of BPD). This test is highly reliable and correlated with discharge home on oxygen, length of hospital stay, and hospital readmissions in the 1st yr of life. The risk of neurodevelopmental impairment and pulmonary morbidity and the severity of BPD are directly correlated.

Table 122.2

Definition of Bronchopulmonary Dysplasia (BPD): Diagnostic Criteria[*]

	GESTATIONAL AGE	
	<32 Wk	**≥32 Wk**
Time point of assessment	36 wk PMA or discharge home, whichever comes first Treatment with >21% oxygen for at least 28 days **plus** :	>28 days but <56 days postnatal age or discharge home, whichever comes first Treatment with >21% oxygen for at least 28 days **plus** :
Mild BPD	Breathing room air at 36 wk PMA or discharge home, whichever comes first	Breathing room air by 56 days postnatal age or discharge home, whichever comes first
Moderate BPD	Need[†] for <30% oxygen at 36 wk PMA or discharge home, whichever comes first	Need[†] for <30% oxygen at 56 days postnatal age or discharge home, whichever comes first
Severe BPD	Need[†] for ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 36 wk PMA or discharge home, whichever comes first	Need[†] for ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 56 days postnatal age or discharge home, whichever comes first

[*] BPD usually develops in neonates being treated with oxygen and PPV for respiratory failure, most frequently respiratory distress syndrome (RDS). Persistence of the clinical features of respiratory disease (tachypnea, retractions, crackles) is considered common to the broad description of BPD and has not been included in the diagnostic criteria describing the severity of BPD. Infants treated with >21% oxygen and/or PPV for nonrespiratory disease (e.g., central apnea or diaphragmatic paralysis) do not have BPD unless parenchymal lung disease also develops and they have clinical features of respiratory distress. A day of treatment with >21% oxygen means that the infant received >21% oxygen for >12 hr on that day. Treatment with >21% oxygen and/or PPV at 36 wk PMA or at 56 days postnatal age or discharge should not reflect an “acute” event, but should rather reflect the infant's usual daily therapy for several days preceding and after 36 wk PMA, 56 days postnatal age, or discharge.

[†] A physiologic test confirming that the oxygen requirement at the assessment time point remains to be defined. This assessment may include a pulse oximetry saturation range.

NCPAP, Nasal continuous positive airway pressure; PMA, postmenstrual age; PPV, positive pressure ventilation.

From Jobe AH, Bancalari E: Bronchopulmonary dysplasia, *Am J Respir Crit Care Med* 163:1723–1729, 2001.

Despite its simplicity, the current severity-based definition of BPD has limitations. Because of incomplete or inaccurate data related to hospital transfer or early discharge, in a significant number of infants the diagnosis of BPD is either not documented or misapplied. Additionally, those infants requiring O_2 support at relatively high flow (>2 L/min) or very low (<0.25 L/min) are not well characterized. Calculation of *effective oxygen* may be helpful but is cumbersome and not well validated. Many clinical trials have simply relied on the need for supplemental O_2 at 36 wk PMA to define BPD. While this definition can diagnose BPD in the highest percentage of infants, it cannot discriminate between infants with milder BPD from those with most severe forms of BPD. In general, any definition of BPD striving to identify infants who benefit from long-term follow up and therapy has been disappointing. Therefore an improved yet feasible definition of BPD is required that accurately evaluates the utility of investigational therapies, predicts long-term outcomes, and directs clinical care.

Prevention

In general, there remains a lack of effective interventions that prevent BPD. Avoidance of mechanical ventilation with the early use of **nCPAP** and early, selective **surfactant** replacement therapy with rapid extubation decrease the incidence of BPD modestly. The avoidance of mechanical ventilation achieved by the combination of early rescue surfactant by the INSURE, MIST, or LISA method with nCPAP has been associated with a modest reduction in BPD. Gentle ventilation strategies, including volume-targeted ventilation and HFOV, have also been associated with small, inconsistent reductions in BPD. **Caffeine** therapy for apnea of prematurity has also been associated with a decreased risk of BPD. Although the mechanisms are unknown, caffeine likely supports effective spontaneous respiration and decreases the likelihood that an infant will need invasive mechanical ventilation.

Animal models of BPD have consistently demonstrated that **vitamin A** supplementation promotes distal alveolar development. Previously, provision of intramuscular (IM) vitamin A (5,000 IU 3 times/wk for 4 wk) to VLBW infants was shown to reduce the risk of BPD (1 case prevented for every 14-15 infants treated). However, with the widespread use of early nCPAP, it is unclear if a significant benefit remains, and therefore the use of vitamin A has been inconsistent. Despite promising preclinical data in animal models, the use of prophylactic iNO does not consistently prevent BPD, and its routine use is not recommended.

Systemic corticosteroids (dexamethasone) given either early (<7 days of age to ventilated infants at risk of BPD) or late (>7 days of age to infants with progressing lung disease) prevent both mortality and BPD significantly, but because of the increased risk of **cerebral palsy (CP)** and **neurodevelopmental impairment** , their routine use is not recommended. The risk of neurodevelopmental impairment related to systemic corticosteroid use may be offset by the risk associated with BPD. A systematic review suggested that systemic corticosteroid therapy, when directed to infants with a ≥65% risk of developing BPD, may actually reduce the risk of neurodevelopmental impairment and CP. Although predictive models that use clinical characteristics have been described with promising accuracy, randomized trials using them to guide corticosteroid therapy have not been performed. Systemic hydrocortisone given early to extremely preterm infants at risk for BPD, especially those exposed to chorioamnionitis, may prevent BPD without neurodevelopmental impairment. However, at this time there are insufficient data on safety to support its routine use. **Inhaled corticosteroids** administered to VLBW infants requiring mechanical ventilation at 7-14 days of age did not prevent BPD significantly. However, early, prolonged administration to mechanically ventilated extremely preterm infants until they no longer require oxygen or positive pressure support has been shown to reduce the risk of BPD, but with a concerning trend toward increased mortality. Experience with local delivery of corticosteroids by spiking surfactant with **budesonide** is emerging, and early data suggest that **endotracheal** administration of corticosteroids may reduce pulmonary inflammation and the risk of BPD and death. However, additional evidence is needed before widespread use is implemented. The routine use of antibiotics, inhaled bronchodilators, or diuretics has not been shown to prevent BPD.

Treatment

Treatment of evolving and established BPD is supportive, and evidence-based therapies are lacking. The basic tenets of therapy should include appropriate support of ventilation and aggressive nutritional support to optimize linear growth and encourage normal lung repair and development. Despite a lack of support from investigational studies in the current era of BPD, numerous medical interventions are employed. Available evidence suggests short-term benefits (improved pulmonary mechanics, modest reductions in respiratory support parameters) without an indication of impact on clinically relevant outcomes (survival, need for long-term respiratory support, recurrent hospitalization). Currently, available evidence does not support the routine use of any pharmacologic agents in infants with evolving or established BPD. Treatment decisions must weigh the perceived benefit against the potential harm, since data on not only efficacy, but more importantly safety, remain inadequate.

Diuretics and Fluid Restriction

Infants with BPD often have excessive pulmonary interstitial fluid that compromises lung function and increases work of breathing. Diuretic therapy (usually with furosemide or chlorothiazide) has been associated with short-term, temporary improvements in pulmonary compliance and the ability to wean respiratory support. **Furosemide** (1 mg/kg/dose IV or 2 mg/kg/dose PO every 12-24 hr) has been demonstrated to decrease pulmonary interstitial emphysema and PVR, improve pulmonary function, and facilitate weaning from mechanical ventilation and oxygen. Adverse effects of long-term furosemide therapy are common and include hyponatremia, hypokalemia, alkalosis, azotemia, hypocalcemia, hypercalciuria, cholelithiasis, renal stones, nephrocalcinosis, and ototoxicity. Potassium chloride supplementation is often necessary. Thiazide diuretics (e.g., chlorothiazide, 5-10 mg/kg/dose every 12 hr) have been used as an alternative to avoid hypercalciuria, limit nephrocalcinosis, and preserve bone development. Although avoidance of excessive fluid administration in the 1st few wk of age is associated with a reduced risk of BPD, there is no evidence that fluid restriction (130-140 mL/kg/day) in established BPD has any impact. Whether using diuretics or fluid restriction, careful attention to maintaining appropriate electrolyte levels as well as providing adequate caloric intake (often >120-130 kcal/kg/day) is paramount to avoid negatively impacting nutrition.

Bronchodilators

Inhaled bronchodilators improve lung mechanics by decreasing airway resistance. **Albuterol** is a specific β_2 -agonist used to treat bronchospasm in infants with BPD. Albuterol may improve lung compliance by decreasing airway resistance secondary to smooth muscle cell relaxation. Changes in pulmonary mechanics may last as long as 4-6 hr. Hypertension and tachycardia are common adverse effects. **Ipratropium bromide** is a muscarinic antagonist related to atropine, but the bronchodilator effect is more potent. Use of ipratropium bromide in BPD has been associated with improved pulmonary mechanics.

Compared to either agent used alone, combined use of albuterol and ipratropium bromide may be more effective. Few adverse effects have been noted. With current aerosol administration strategies, exactly how much medication is delivered to the airways and lungs of infants with BPD, especially if they are ventilator dependent, is unclear.

Corticosteroids

In addition to their use at an early age (<7 days) to prevent BPD, **systemic corticosteroids** have also been used to treat evolving and established BPD. In mechanically ventilated infants, systemic corticosteroids improve pulmonary mechanics, allow weaning of ventilator support and supplemental O_2 , and facilitate extubation. When given at >7 days of age, long-term benefits include a reduced need for O_2 at 36 wk PMA, improved survival, and decreased need for home O_2 . Short-term adverse effects include hyperglycemia, hypertension, and transient hypertrophic obstructive cardiomyopathy. Long-term adverse effects include osteopenia, severe retinopathy of prematurity (ROP), abnormal neurological examination, poor brain growth, neurodevelopmental impairment, and CP. Although meta-analyses suggest that the long-term detrimental effects on neurodevelopment might be mitigated by later postnatal use, open-label use of corticosteroids in control groups makes analysis of safety unreliable. A strategy that utilizes a low cumulative dose (0.89 mg/kg given over 10-day taper) in preterm infants who remain ventilator dependent after 7 days of age (and therefore have a high risk of developing BPD) facilitates weaning of ventilator and oxygen support and promotes successful extubation without an impact on long-term outcomes, including the incidence of BPD or neurodevelopmental impairment. However, randomized controlled trials (RCTs) with appropriate power to assess safety are lacking. The controversy concerning the appropriate use of systemic corticosteroids to prevent and/or treat BPD is ongoing, and until additional evidence is available, their use remains limited to infants with severe respiratory failure (ventilator dependent at >7-14 days of age with significant respiratory and oxygen support needs) at high risk for imminent death.

In an effort to avoid the detrimental effects of systemic corticosteroids, **inhaled corticosteroids** (budesonide, fluticasone, and beclomethasone) have been described as an alternative antiinflammatory therapy in evolving or established BPD. Small RCTs and case reports in infants with established moderate-severe BPD have not shown a significant benefit for pulmonary mechanics or reduction in the need for ventilator or oxygen support.

Pulmonary Vasodilators

Many infants with evolving or established moderate and severe BPD demonstrate pulmonary vascular resistance caused by pulmonary microvascular maldevelopment and abnormal vasoreactivity. In infants with BPD with pulmonary hypertension, acute exposure to even modest levels of hypoxemia can cause pulmonary artery pressure (PAP) to increase abruptly. Maintaining infants with established BPD and pulmonary hypertension at higher SO_2 targets (92–96%) can lower PAP effectively. For infants in whom appropriate O_2 supplementation and support of ventilation are ineffective, the use of low-dose **inhaled NO** may improve oxygenation anecdotally. Despite its frequent use, there is no evidence to support the use of iNO to improve lung function, cardiac function, or oxygenation in evolving BPD. Several case series have reported on the use of the phosphodiesterase-5 inhibitor **sildenafil** in treating pulmonary hypertension in established moderate to severe BPD. Despite its widespread use, no RCTs are evaluating the safety and efficacy of sildenafil in preterm infants with BPD. However, many experts would recommend a trial of low-dose sildenafil (1 mg/kg/dose every 8 hr) for infants with evidence of pulmonary hypertension and persistent respiratory instability despite appropriate oxygen and ventilator support.

Chronic Respiratory Support

Evidence is lacking to guide respiratory management in evolving and established BPD. Experience suggests that maintaining FRC with appropriate positive pressure support (with noninvasive support whenever possible) promotes optimal lung growth and development. Provision of nCPAP until respiratory status improves and oxygen dependence resolves, with subsequent transition directly to room air, may be beneficial but is not based on evidence. Continuation of caffeine therapy may facilitate spontaneous breathing and weaning from support. Established severe BPD with cystic, heterogeneous lung disease requires prolonged mechanical ventilation. A long inspiratory time is required to adequately ventilate diseased lung units, and appropriate expiratory time is required to allow exhalation. The use of a low rate (<20-30 breaths/min), long inspiratory time (≥0.6 sec) strategy is usually required. To attain appropriate minute ventilation, larger tidal volumes (10-12 mL/kg) are necessary. Higher PEEP (often >6-8 cm) may be needed to attain adequate expansion and minimize gas-trapping caused by dynamic airway collapse. Gradual weaning of ventilator settings should be attempted as the infant grows and lung disease improves, but the incidence of death or tracheostomy placement for chronic ventilation may be as high as 20%. By 2-3 yr of age, the majority of infants who undergo tracheostomy for severe BPD are successfully liberated from mechanical ventilation.

Prognosis

Compared with extremely preterm infants without BPD, infants with BPD have higher rates of neurodevelopmental impairment, lung diffusion impairment, wheezing and airflow obstruction, rehospitalization, and mortality. The risk of these complications increases with BPD severity. Prolonged mechanical ventilation, IVH, pulmonary hypertension, cor pulmonale, and oxygen dependence beyond 1 yr of life are poor prognostic signs. Mortality in infants with BPD ranges from 10–25% and is highest in infants who remain ventilator dependent for >6 mo. Cardiorespiratory failure associated with cor pulmonale and acquired infection (respiratory syncytial virus) are common causes of death. Infants are at risk for severe RSV infections and must receive prophylactic therapy (see Chapter 287).

Pulmonary function slowly improves in most survivors because of ongoing lung repair and the natural period of lung growth and alveolarization. *Rehospitalization* for impaired pulmonary function is most common during the 1st 3 yr of life and is much more common in infants requiring respiratory support at discharge. The incidence of physician-diagnosed asthma, use of bronchodilators, and wheezing is elevated. Despite a gradual decrease in symptom frequency, persistence of respiratory symptoms and abnormal pulmonary function test results are measurable in children, adolescence, and young adults. Although not always clinically apparent, pulmonary function testing consistently reveals impaired exercise capacity, reduced pulmonary diffusing capacity, and persistent expiratory flow obstruction. High-resolution chest CT scanning or MRI studies in children and adults with a history of BPD reveal lung abnormalities that correlate directly with the degree of pulmonary function abnormality. The ultimate long-term pulmonary health of survivors of

BPD is unknown. As trajectories of developing lung function remain abnormal in survivors of BPD, concerns have been raised highlighting the potential for pulmonary emphysema, chronic obstructive pulmonary disease, and pulmonary vascular disease resulting in early debilitating lung dysfunction.

Other complications of BPD include growth failure, neurodevelopmental impairment, and parental stress, as well as sequelae of therapy, such as nephrolithiasis, osteopenia, and electrolyte imbalance. Airway problems such as vocal cord paralysis, subglottic stenosis, and tracheomalacia are common and may aggravate or cause pulmonary hypertension. Subglottic stenosis may require tracheotomy or an anterior cricoid split procedure to relieve upper airway obstruction. Cardiac complications of BPD include pulmonary hypertension, cor pulmonale, systemic hypertension, left ventricular hypertrophy, and development of aortopulmonary collateral vessels, which, if large, may cause heart failure.

Patent Ductus Arteriosus

Shawn K. Ahlfeld

Keywords

patent ductus arteriosus
PDA
indomethacin
ibuprofen
cyclooxygenase inhibitors
surgical ligation

Incidence and Pathophysiology

Some neonates with RDS may have clinically significant shunting through a patent ductus arteriosus (**PDA**). Although ductal closure occurs by 72 hr after birth in almost all term infants, at the same age in 65% of preterm infants born at <30 wk GA, the ductus remains patent. Risk factors for delayed closure of the PDA include hypoxia, acidosis, increased pulmonary pressure secondary to vasoconstriction, systemic hypotension, immaturity, and local release of prostaglandins (which dilate the ductus). Shunting through the PDA may initially be bidirectional or right to left. As respiratory distress syndrome (RDS) resolves, pulmonary vascular resistance (PVR) decreases, and left-to-right shunting may occur, leading to left ventricular (LV) volume overload and pulmonary edema.

Clinical Manifestations

Manifestations of PDA may include (1) a hyperdynamic precordium, bounding peripheral pulses, wide pulse pressure, and a machine-like continuous or systolic murmur; (2) radiographic evidence of cardiomegaly and increased pulmonary vascular markings; (3) hepatomegaly; (4) increasing oxygen dependence; (5) carbon dioxide retention; and (6) renal failure. Infants with a hemodynamically significant PDA often require escalation of ventilator and oxygen support. The diagnosis is confirmed by echocardiographic visualization of a PDA with Doppler flow imaging that demonstrates left-to-right or bidirectional shunting.

Treatment

Management of the PDA is controversial, and evidence to guide treatment is limited. Prophylactic closure before signs of a PDA, closure of the asymptomatic but clinically detected PDA, and closure of the symptomatic PDA are 3 management strategies. Interventions to encourage ductal closure include fluid restriction, cyclooxygenase (COX) inhibitors (indomethacin or ibuprofen), and surgical ligation. Short-term benefits of any therapy have to be balanced against adverse effects, such as transient renal dysfunction and fluid imbalances associated with indomethacin.

By the time of discharge in the majority of extremely preterm infants (>90%), the PDA will close spontaneously. Spontaneous ductal closure may be facilitated by general supportive measures, including early (<7 days of age) avoidance of excessive fluid administration and judicious use of diuretics to manage pulmonary edema. However, within the 1st week of age, in 30% of infants with birthweight <1,500 g and 70% of infants <1,000 g, the PDA persists. Although many preterm infants with persistent PDA will remain clinically stable while awaiting spontaneous closure, approximately 60% of infants <1,000 g will develop significant clinical instability (hypotension, renal failure, worsening respiratory failure secondary to pulmonary edema). Pharmacologic and surgical ductal closure may be indicated in the premature infant with a moderate to large, hemodynamically significant PDA when there is a delay in clinical improvement or deterioration.

Pharmacologic Closure

Pharmacologic closure of the PDA has been described using COX inhibitors that inhibit prostaglandin production, with equivalent efficacy and safety profiles described for ibuprofen and indomethacin. The efficacy of pharmacological therapy is inversely proportional to the gestational and postnatal age, and closure is more likely when medication is administered before 14-21 days of age. However, successful closure has been reported up to 8 wk of age. Whether indomethacin or ibuprofen is used, 20–40% of infants demonstrate treatment failure, and of those infants, 10–20% require eventual surgical ligation. Rates of recurrence following successful pharmacologic closure in general are low (<15%). Neither therapy significantly impacts the rate of NEC, BPD, or mortality. **General contraindications** to both indomethacin and ibuprofen include thrombocytopenia (<50,000 platelets/mm^3), active hemorrhage (including severe IVH), NEC or isolated intestinal perforation, elevated plasma creatinine (>1.8 mg/dL), or oliguria (urine output <1 mL/kg/hr).Importantly, the concomitant use of hydrocortisone and indomethacin in extremely preterm infants must be avoided, because the combination is associated with a dramatic increase in spontaneous intestinal perforation. Despite that indomethacin reduces mesenteric blood flow, mounting experience suggests that low-volume trophic enteral feeding during administration is safe.

Prophylactic **indomethacin** given over the 1st 72 hr of age to preterm infants with birthweight <1,000 g reduces the incidence of severe IVH (grade III/IV), pulmonary hemorrhage, symptomatic PDA, and need for surgical PDA ligation. Although often implicated in spontaneous intestinal perforation and NEC, RCTs have failed to demonstrate that indomethacin increases their risk significantly. Short-term side effects include reductions in cerebral, mesenteric, and renal blood flow. Oliguria unresponsive to diuretic therapy is observed frequently. Dosing regimens for indomethacin vary considerably, but it usually is administered as a slow IV infusion (0.1-0.2 mg/kg/dose over 30 min) every 12-24 hr for 3 doses. A repeat course can be attempted if the duct fails to close or reopens, but additional (>2) courses do not appear to be efficacious. Longer courses (5-7 days) of indomethacin are not recommended because of to an increased risk of NEC in one trial.

Ibuprofen is as effective as indomethacin in closing a PDA, but ibuprofen is associated with reduced rates of oliguria and a small but significant reduction in the length of mechanical ventilation. Although higher doses may improve closure rates in the most immature infants, the typical IV or enteral dosing regimen for ibuprofen is 10 mg/kg for 1 dose, followed by 2 doses of 5 mg/kg every 24 hr. As with indomethacin, a repeat course may be considered, but additional courses of ibuprofen are not efficacious and not recommended. Risk of NEC is not increased with indomethacin, but ibuprofen reduces the relative risk of NEC comparatively. Unlike indomethacin, ibuprofen has not been shown to reduce the risk of severe IVH. Compared to the IV route, enteral ibuprofen may be more efficacious. Whether ibuprofen used in combination with hydrocortisone results in increased risk of spontaneous intestinal perforation is unknown.

Preliminary studies suggest that **acetaminophen** may be an effective drug to close a PDA, with fewer side effects than existing agents.

Surgical Ligation

The infant whose symptomatic PDA fails to close with pharmacologic interventions or who has contraindications to COX inhibitors is a candidate for surgical closure. Although the long-term benefits are unclear, surgical ligation in infants born at <28 wk GA and <1,250 g is associated with improved survival. Surgical mortality is very low even in ELBW infants. However, **postligation cardiac syndrome** , a significant drop in blood pressure 6-12 hr after ductal ligation, is experienced by up to 50% of LBW infants. The hypotension has been attributed to increased systemic vascular resistance along with decreased pulmonary venous return, resulting in impaired preload and LV function. Fluid resuscitation, inotropic support (with dobutamine or milrinone), and hydrocortisone are usually effective. Other complications of surgery include hemorrhage, pneumothorax, chylothorax, Horner syndrome, and injury to the recurrent laryngeal nerve resulting in vocal cord dysfunction. Inadvertent ligation of the left pulmonary artery or the transverse aortic arch has rarely been reported. Increased rates of neurodevelopmental impairment have been reported following surgical ligation, although a causal relationship remains uncertain.

122.6

Transient Tachypnea of the Newborn

Shawn K. Ahlfeld

Keywords

transient tachypnea of the newborn
TTN
fetal lung fluid
albuterol
salbutamol

Transient tachypnea of the newborn (**TTN**) is a clinical syndrome of self-limited tachypnea associated with delayed clearance of fetal lung fluid. Although the actual incidence is likely underreported, it is estimated at 3-6 per 1,000 term infant births, making TTN the most common etiology of tachypnea in the newborn. Twin gestation, maternal asthma, late prematurity, precipitous delivery, gestational diabetes, and cesarean delivery without labor are common associated risk factors. Clearance of fetal lung fluid occurs through increased expression of epithelial sodium channels (ENaC) and sodium-potassium adenosine triphosphatase (Na^+ ,K^+ -ATPase) that drive active sodium (and thereby fluid) reabsorption. TTN is believed to result from ineffective expression or activity of ENaC and Na^+ ,K^+ -ATPase, which slows absorption of fetal lung fluid and results in decreased pulmonary compliance and impeded gas exchange.

TTN is characterized by the early onset of tachypnea (>60 breaths/min), sometimes with retractions or expiratory grunting and occasionally with cyanosis that is relieved by minimal O_2 supplementation (<40%). The chest generally sounds clear without crackles or wheeze, and the chest radiograph shows prominent perihilar pulmonary vascular markings, fluid in the intralobar fissures, and rarely small pleural effusions. Hypercapnia and acidosis are uncommon. Respiratory failure requiring positive pressure support (either with nCPAP or mechanical ventilation) also is uncommon, but when it occurs usually resolves rapidly (<12-24 hr). Most infants recover with supportive care alone, and over the first 24-72 hours the tachypnea and O_2 requirements slowly resolve. Distinguishing TTN from RDS and other respiratory disorders (e.g., pneumonia) may be difficult, and transient tachypnea is frequently a diagnosis of exclusion. The distinctive features of TTN are rapid recovery of the infant and the absence of radiographic findings for RDS (low lung volumes, diffuse reticulogranular pattern, air bronchograms) and other lung disorders.

Treatment for TTN is supportive. There is no evidence supporting the use of oral furosemide or nebulized racemic epinephrine in this disorder. Inhaled β_2 -agonists such as albuterol (salbutamol) increase expression and activation of ENaC and Na^+ ,K^+ -ATPase and facilitate fluid clearance. Emerging evidence suggests that when given early in the course of TTN, albuterol may improve oxygenation, shorten the duration of supplemental O_2 therapy, and expedite recovery.

122.7

Aspiration of Foreign Material (Fetal Aspiration Syndrome, Aspiration Pneumonia)

Shawn K. Ahlfeld

Keywords

aspiration pneumonia
tracheoesophageal fistula
gastroesophageal reflux

With fetal distress, infants often initiate vigorous respiratory movements in utero because of interference with the supply of oxygen through the placenta. Under such circumstances, the infant may aspirate amniotic fluid containing vernix caseosa, epithelial cells, meconium, blood, or material from the birth canal, which may block the smallest airways and interfere with alveolar exchange of O_2 and CO_2 . Pathogenic bacteria may accompany the aspirated material, and pneumonia may ensue, but even in noninfected cases, respiratory distress accompanied by radiographic evidence of aspiration is seen (Fig. 122.7).

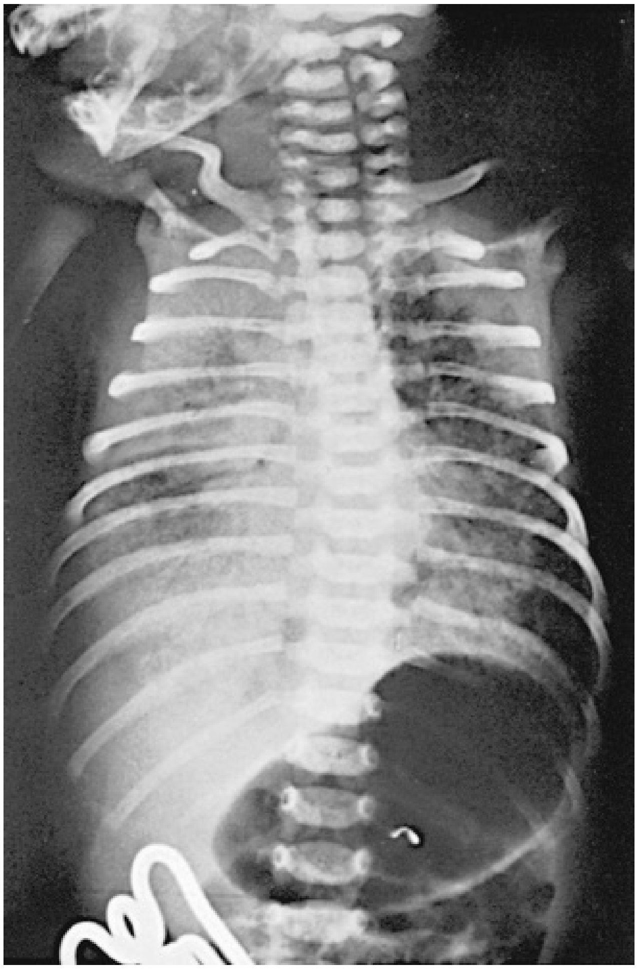

FIG. 122.7 Fetal aspiration syndrome (aspiration pneumonia). Note the coarse granular pattern with irregular aeration typical of fetal distress from the aspiration of material contained in amniotic fluid, such as vernix caseosa, epithelial cells, and meconium. (From Goodwin SR, Grave SA, Haberkern CM: Aspiration in intubated premature infants, *Pediatrics* 75:85–88, 1985.)

Postnatal pulmonary aspiration may also occur in newborn infants as a result of prematurity, tracheoesophageal fistula, esophageal and duodenal obstruction, gastroesophageal reflux, improper feeding practices, and administration of depressant medicines. To avoid aspiration of gastric contents, the stomach should be aspirated using a soft catheter just before surgery or other major procedures that require anesthesia or conscious sedation. The treatment of **aspiration pneumonia** is symptomatic and may include respiratory support and systemic antibiotics. Gradual improvement generally occurs over 3-4 days.

122.8

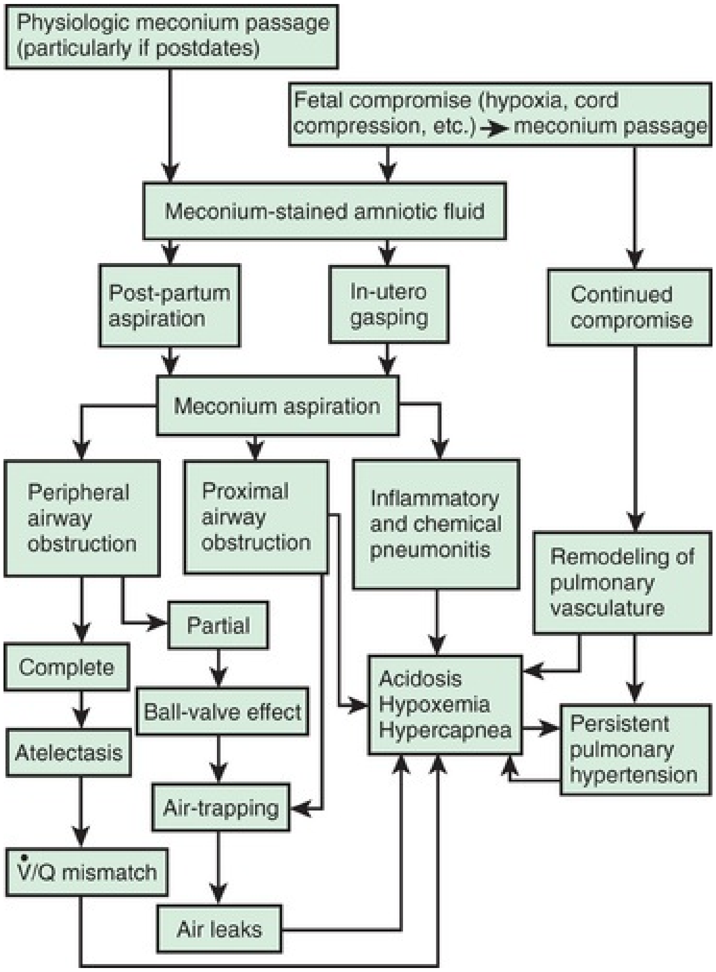
Meconium Aspiration

Shawn K. Ahlfeld

Keywords

meconium aspiration syndrome
MAS
persistent pulmonary hypertension
pneumothorax

Meconium-stained amniotic fluid is found in 10–15% of births and usually occurs in term or postterm infants. **Meconium aspiration syndrome (MAS)** develops in 5% of such infants; 30% require mechanical ventilation, and 3–5% die. Usually, but not invariably, fetal distress and hypoxia occur before the passage of meconium into amniotic fluid. The infants are meconium stained and may be depressed and require resuscitation at birth. Fig. 122.8 shows the pathophysiology of the MAS. Infants with MAS are at increased risk of **persistent pulmonary hypertension** (see Chapter 122.9).



Physiologic meconium passage (particularly if postdates)

FIG. 122.8 Pathophysiology of meconium passage and the meconium aspiration syndrome. V̇/Q̇, Ventilation-perfusion ratio. (From Wiswell TE, Bent RC: Meconium staining and the meconium aspiration syndrome: unresolved issues, *Pediatr Clin North Am* 40:955–981, 1993.)

Clinical Manifestations

Either in utero or with the first breath, thick, particulate meconium is aspirated into the lungs. The resulting small airway obstruction may produce respiratory distress within the 1st hours, with tachypnea, retractions, grunting, and cyanosis observed in severely affected infants. Partial obstruction of some airways may lead to pneumomediastinum, pneumothorax, or both. Overdistention of the chest may be prominent. The condition usually improves within 72 hr, but when its course requires assisted ventilation, it may be severe with a high risk for mortality. Tachypnea may persist for many days or even several weeks. The typical chest radiograph is characterized by patchy infiltrates, coarse streaking of both lung fields, increased anteroposterior diameter, and flattening of the diaphragm. A normal chest radiograph in an infant with severe hypoxemia and no cardiac malformation suggests the diagnosis of pulmonary hypertension.

Prevention

The risk of meconium aspiration may be decreased by rapid identification of fetal distress and initiation of prompt delivery in the presence of late fetal heart rate deceleration or poor beat-to-beat FHR variability. Despite initial enthusiasm for amnioinfusion, it does not reduce the risk of MAS, cesarean delivery, or other major indicators of maternal or neonatal morbidity. Intrapartum nasopharyngeal suctioning in infants with meconium-stained amniotic fluid does not reduce the risk for MAS. Routine intubation and aspiration of depressed infants (those with hypotonia, bradycardia, or decreased respiratory effort) born through meconium-stained fluid is not effective in reducing the MAS or other major adverse outcomes and is not recommended for neonatal resuscitation.

Treatment

Treatment of the MAS includes supportive care and standard management for respiratory distress. The beneficial effect of mean airway pressure on oxygenation must be weighed against the risk of pneumothorax. Administration of exogenous surfactant and/or iNO to infants with MAS and hypoxemic respiratory failure, or pulmonary hypertension requiring mechanical ventilation, decreases the need for extracorporeal membrane oxygenation (ECMO), which is required by the most severely affected infants who show no response to therapy. In infants with MAS who demonstrate no other signs of sepsis, there is no role for routine antibiotic therapy. Severe meconium aspiration may be complicated by persistent pulmonary hypertension. Patients with MAS refractory to conventional mechanical ventilation may benefit from HFV or ECMO (see Chapter 122.9).

Prognosis

The mortality rate of meconium-stained infants is considerably higher than that of nonstained infants. The decline in neonatal deaths caused by MAS in recent decades is related to improvements in obstetric and neonatal care. Residual lung problems are rare but include symptomatic cough, wheezing, and persistent hyperinflation for up to 5-10 yr. The ultimate prognosis depends on the extent of CNS injury from asphyxia and the presence of associated problems such as pulmonary hypertension.

122.9

Persistent Pulmonary Hypertension

# of the Newborn (Persistent Fetal Circulation)

Shawn K. Ahlfeld

Keywords

persistent pulmonary hypertension of the newborn
PPHN
persistent fetal circulation
extracorporeal membrane oxygenation
ECMO
inhaled nitric oxide
iNO
sildenafil
high-frequency oscillatory ventilation
HFOV
alveolocapillary dysplasia
ACD

Persistent pulmonary hypertension of the newborn (**PPHN**) occurs in term and postterm infants most often. Predisposing factors include birth asphyxia, MAS, early-onset sepsis, RDS, hypoglycemia, polycythemia, maternal use of nonsteroidal antiinflammatory drugs with in utero constriction of the ductus arteriosus, maternal late trimester use of selective serotonin reuptake inhibitors, and pulmonary hypoplasia caused by diaphragmatic hernia, amniotic fluid leak, oligohydramnios, or pleural effusions. PPHN is often idiopathic. Some patients with PPHN have low plasma arginine and NO metabolite concentrations and polymorphisms of the carbamoyl phosphate synthase gene, findings suggestive of a possible subtle defect in NO production. The incidence is 1 in 500-1,500 live births, with a wide variation among clinical centers. Regardless of etiology of PPHN, profound hypoxemia from right-to-left shunting and normal or elevated $PaCO_2$ are present (Fig. 122.9).

(From Kinsella JP, Abman SH: Recent developments in the pathophysiology and treatment of persistent pulmonary hypertension of the newborn, *J Pediatr* 126:853–864, 1995.)**

Pathophysiology

Persistence of the fetal circulatory pattern of right-to-left shunting through the PDA and foramen ovale after birth is a result of excessively high pulmonary vascular resistance (PVR). Fetal PVR is usually elevated relative to fetal systemic or postnatal pulmonary pressure. This fetal state normally permits shunting of oxygenated umbilical venous blood to the left atrium (and brain) through the foramen ovale, from which it bypasses the lungs through the ductus arteriosus and passes to the descending aorta. After birth, PVR normally declines rapidly as a consequence of vasodilation secondary to lung inflation, a rise in postnatal PaO_2 , a reduction in $PaCO_2$, increased pH, and release of vasoactive substances. Increased neonatal PVR may be (1) **maladaptive** from an acute injury (not demonstrating normal vasodilation in response to increased O_2 and other changes after birth); (2) the result of increased pulmonary artery medial muscle thickness and extension of smooth muscle layers into the usually nonmuscular, more peripheral pulmonary arterioles in response to chronic fetal hypoxia; (3) a consequence of **pulmonary hypoplasia** (diaphragmatic hernia, Potter syndrome); or (4) **obstructive** as a result of polycythemia, total anomalous pulmonary venous return (TAPVR), or congenital diffuse development disorders of acinar lung development.

Clinical Manifestations

PPHN usually manifests in the delivery room or within the 1st 12 hr after birth. Idiopathic PPHN or PPHN related to polycythemia, hypoglycemia, hypothermia, or asphyxia may result in severe cyanosis and respiratory distress. In some cases, however, initial signs of respiratory distress may be minimal. Infants who have PPHN associated with meconium aspiration, group B streptococcal pneumonia, diaphragmatic hernia, or pulmonary hypoplasia usually exhibit cyanosis, grunting, flaring, retractions, tachycardia, and shock. Multiorgan involvement may be present (see Table 119.2). Myocardial ischemia, papillary muscle dysfunction with mitral and tricuspid regurgitation, and biventricular dysfunction produce cardiogenic shock with decreases in pulmonary blood flow, tissue perfusion, and O_2 delivery.

Hypoxemia is often labile and out of proportion to the findings on chest radiographs. In asphyxia-associated and idiopathic PPHN, chest x-ray findings are often normal, whereas in PPHN associated with **pneumonia** and **diaphragmatic hernia** , parenchymal opacification and bowel/liver in the chest, respectively, are seen.

Diagnosis

Independent of the prenatal history, PPHN should be suspected in all term infants who have cyanosis. Hypoxemia is universal and intermittently unresponsive to 100% O_2 given by oxygen hood. A transient improvement may occur in response to hyperoxic hyperventilation administered by positive pressure ventilation. A PaO_2 or SaO_2 gradient between a preductal (right radial artery) and a postductal (umbilical artery) site of blood sampling suggests right-to-left shunting through the ductus arteriosus. Intracardiac shunting through the patent foramen ovale does not lead to a Pa_{O_2} or Sa_{O_2} gradient.

Real-time echocardiography combined with Doppler flow imaging is very helpful in evaluating PPHN. Systolic flattening of the interventricular septum as the right ventricular systolic pressure approaches the left ventricular systolic pressure can be used to estimate the degree of pulmonary hypertension. The peak velocity of the tricuspid valve regurgitation jet, when present, yields a quantitative estimate of the right ventricular systolic pressure. Likewise, the direction and velocity of a shunt across the PDA provides a quantitative comparison between the aortic and pulmonary artery pressures. In advanced cases, right-to-left or bidirectional shunting across a PDA and a patent foramen ovale can be observed.

The differential diagnosis of PPHN includes cyanotic heart disease (especially obstructed TAPVR), idiopathic pulmonary vein stenosis, congenital surfactant deficiency syndromes, pulmonary artery thrombosis, and congenital diffuse development disorders of acinar lung development (acinar dysplasia, congenital alveolar dysplasia, and alveolar capillary dysplasia with misalignment of the pulmonary veins).

Alveolocapillary dysplasia (ACD) is a rare, highly lethal autosomal recessive disorder of distal lung development characterized by immature lobular development and reduced capillary density. Infants with ACD present with idiopathic PPHN, demonstrating little or no parenchymal lung disease and profound hypoxemia. Over 60% of infants with ACD manifest hypoxemia and respiratory failure within 48 hr of birth, while some with milder disease present beyond 6 mo of age. The diagnosis is made on autopsy in 90% of cases, and the constellation of findings include thickened alveolar septa, increased muscularization of the pulmonary arterioles, a reduced number of capillaries, with the remaining capillaries demonstrating abnormal apposition to the air interface, and misalignment of the intrapulmonary veins. In up to 80% of cases, extrapulmonary malformations of the genitourinary, gastrointestinal, or cardiovascular system are present. Mutations in the transcription factor gene *FOXFI* have been identified in up to 40% of cases, but the diagnosis continues to rest on clinical and histopathologic features. ACD is uniformly lethal and should be suspected in infants with idiopathic PPHN who fail to respond to maximal medical therapy, or when symptoms recur after successful weaning from ECMO. In a United Kingdom ECMO report, up to 14% of infants who failed ECMO ultimately were diagnosed with ACD. Regardless of the timing of presentation, ACD is uniformly fatal, and lung transplantation remains the sole, experimental therapy.

Treatment

Therapy for PPHN is directed toward correcting any predisposing condition (e.g., hypoglycemia, polycythemia) and improving poor tissue oxygenation. The response to therapy is often unpredictable, transient, and complicated by the adverse effects of drugs or mechanical ventilation. Initial management includes O_2 administration and correction of acidosis, hypotension, and hypercapnia. Persistent hypoxemia should be managed with intubation and mechanical ventilation.

Infants with PPHN are usually managed without hyperventilation or alkalization. Gentle ventilation with normocarbia or permissive hypercarbia and avoidance of hypoxemia result in excellent outcomes and a low incidence of chronic lung disease and ECMO use.

Because of their instability and ability to fight the ventilator, newborns with PPHN usually require **sedation** . The use of paralytic agents is controversial and reserved for the newborn who cannot be treated with sedatives alone. Muscle relaxants may promote atelectasis of dependent lung regions and ventilation-perfusion mismatch and may be associated with an increased risk of death.

Inotropic therapy is frequently needed to support blood pressure and perfusion. Whereas dopamine is frequently used as a first-line agent, other agents, such as dobutamine, epinephrine, and milrinone, may be helpful when myocardial contractility is poor. Some of the sickest newborns with PPHN demonstrate hypotension refractory to vasopressor administration. This results from desensitization of the cardiovascular system to catecholamines by overwhelming illness and relative adrenal insufficiency. Hydrocortisone rapidly upregulates cardiovascular adrenergic receptor expression and serves as a hormone substitute in cases of adrenal insufficiency.

Inhaled NO is an endothelium-derived signaling molecule that relaxes vascular smooth muscle and can be delivered to the lung by inhalation. *Use of iNO reduces the need for ECMO support by approximately 40%.* The optimal starting dose is 20 ppm. Higher doses have not been shown to be more effective and are associated with side effects, including methemoglobinemia and increased levels of nitrogen dioxide, a pulmonary irritant. Most newborns require iNO for <5 days. Although NO has been used as long-term therapy in children and adults with primary pulmonary hypertension, prolonged dependency is rare in neonates and suggests the presence of lung hypoplasia, congenital heart disease, or ACD. The maximal safe duration of iNO therapy is unknown. The infant can be weaned to 5 ppm after 6-24 hr of therapy. The dose can then be reduced slowly and discontinued when FIO_2 is <0.6 and the iNO dose is 1 ppm. Abrupt discontinuation should be avoided because it may cause rebound pulmonary hypertension. iNO should be used only at institutions that offer ECMO support or have the capability of transporting an infant on iNO therapy if a referral for ECMO is necessary. Some infants with PPHN do not respond adequately to iNO. Therapy with continuous inhaled or IV prostacyclin (prostaglandin I_2) has improved oxygenation and outcome in infants with PPHN. The safety and efficacy of sildenafil (type 5 phosphodiesterase inhibitor) in newborns with PPHN is under investigation; initial results are promising.

In 5–10% of patients with PPHN, the response to 100% O_2, mechanical ventilation, and drugs is poor, and many of these infants benefit from ECMO. In such patients, 2 parameters have been used to predict mortality: the alveolar-arterial oxygen gradient ($PA\text{-}aO_2$), and the oxygenation index (OI), calculated as FIO_2 (as %) × MAP/PaO_2. A $PA\text{-}aO_2$ >620 for 8-12 hr and OI >40 unresponsive to iNO predict a high mortality rate (>80%) and are indications for ECMO. In carefully selected, severely ill infants with hypoxemic respiratory failure caused by RDS, meconium aspiration pneumonia, congenital diaphragmatic hernia, PPHN, or sepsis, ECMO significantly improves survival.

ECMO is a form of cardiopulmonary bypass that augments systemic perfusion and provides gas exchange. Most experience has been with *venoarterial bypass*, which requires carotid artery ligation and the placement of large catheters in the right internal jugular vein and carotid artery. *Venovenous bypass* avoids carotid artery ligation and provides gas exchange, but it does not support cardiac output. Blood is initially pumped through the ECMO circuit at a rate that approximates 80% of the estimated cardiac output, 150-200 mL/kg/min. Venous return passes through a membrane oxygenator, is rewarmed, and returns to the aortic arch in venoarterial ECMO and to the right atrium in venovenous ECMO. Venous O_2 saturation values are used to monitor tissue O_2 delivery and subsequent extraction for infants undergoing venoarterial ECMO, whereas arterial O_2 saturation values are used to monitor oxygenation for infants receiving venovenous ECMO.

Because ECMO requires complete heparinization to prevent clotting in the circuit, its use is generally avoided in patients with existing intracranial hemorrhage or who are at high risk of developing IVH (weight <2 kg, gestational age <34 wk). In addition, infants being considered for ECMO should have reversible lung disease, no signs of systemic bleeding, and no severe asphyxia or lethal malformations, and they should have been ventilated for <10 days. Complications of ECMO include thromboembolism, air embolization, bleeding, stroke, seizures, atelectasis, cholestatic jaundice, thrombocytopenia, neutropenia, hemolysis, infectious complications of blood transfusions, edema formation, and systemic hypertension.

Prognosis

Survival in patients with PPHN varies with the underlying diagnosis. The long-term outcome for infants with PPHN is related to the associated **hypoxic-ischemic encephalopathy** and the ability to reduce PVR. The long-term prognosis for infants who have PPHN and who survive after treatment with hyperventilation is comparable to that for infants who have underlying illnesses of equivalent severity (e.g., birth asphyxia, hypoglycemia, polycythemia). The outcome for infants with PPHN who are treated with ECMO is also favorable; >80–90% survive, and 60–75% of survivors appear normal at 1-3.5 yr of age.

A *diaphragmatic hernia* is defined as a communication between the abdominal and thoracic cavities with or without abdominal contents in the thorax (Fig. 122.10). The etiology is rarely traumatic and usually congenital. The symptoms and prognosis depend on the location of the defect and associated anomalies. The defect may be at the esophageal hiatus (**hiatal hernia**); paraesophageal, adjacent to the hiatus (**paraesophageal hernia** ; Chapter 122.12); retrosternal (**foramen of Morgagni hernia** ; Chapter 122.11); or at the posterolateral portion of the diaphragm (**Bochdalek hernia**). In **congenital diaphragmatic hernia (CDH)** the Bochdalek hernia accounts for up to 90% of the hernias seen, with 80–90% occurring on the left side. The Morgagni hernia accounts for 2–6% of CDH. The size of the defect is highly variable, ranging from a small hole to complete agenesis of this area of the diaphragm. These lesions may cause significant respiratory distress at birth, can be associated with other congenital anomalies, and have significant mortality and long-term morbidity. The overall survival from the CDH Study Group is approximately 70%, but survival is >80% at many centers.

Congenital Diaphragmatic Hernia (Bochdalek)

Pathology and Etiology

Although CDH is characterized by a structural diaphragmatic defect, a major limiting factor for survival is the associated **pulmonary hypoplasia** . Lung hypoplasia was initially thought to be solely caused by the compression of the lung from the herniated abdominal contents, which impaired lung growth. However, emerging evidence indicates that pulmonary hypoplasia, at least in some cases, may precede the development of the diaphragmatic defect.

Pulmonary hypoplasia is characterized by a reduction in pulmonary mass and the number of bronchial divisions, respiratory bronchioles, and alveoli. The pathology of pulmonary hypoplasia and CDH includes abnormal septa in the terminal saccules, thickened alveoli, and thickened pulmonary arterioles. Biochemical abnormalities include relative surfactant deficiencies, increased glycogen in the alveoli, and decreased levels of phosphatidylcholine, total DNA, and total lung protein, all of which contribute to limited gas exchange.

Epidemiology

The incidence of CDH is between 1 in 2,000 and 1 in 5,000 live births, with females affected twice as often as males. Defects are more common on the left (85%) and are occasionally bilateral (<5%). Pulmonary hypoplasia and malrotation of the intestine are part of the lesion, not associated anomalies. Most cases of CDH are sporadic, but familial cases have been reported. Associated anomalies have been reported in up to 30% of cases, including CNS lesions, esophageal atresia, omphalocele, and cardiovascular lesions. CDH is recognized as part of several chromosomal syndromes: trisomies 21, 13, and 18 and Fryns, Brachmann–de Lange, Pallister-Killian, and Turner syndromes.

Diagnosis and Clinical Presentation

In >50% of cases, CDH can be diagnosed on prenatal ultrasonography (US) between 16 and 24 wk of gestation. High-speed fetal MRI can further define the lesion. US findings may include polyhydramnios, chest mass, mediastinal shift, gastric bubble or a liver in the thoracic cavity, and fetal hydrops. Certain imaging features may predict outcome; these include liver position in the chest, observed-to-expected total lung volume (TLV), and observed-to-expected lung-to-head ratio (LHR). Nonetheless, no definitive characteristic reliably predicts outcome. After delivery, a chest radiograph is needed to confirm the diagnosis (Fig. 122.11). In some infants with an echogenic chest mass, further imaging is required. The differential diagnosis may include other diaphragm disorders, such as eventration or a cystic lung lesion (pulmonary sequestration, cystic adenomatoid malformation).

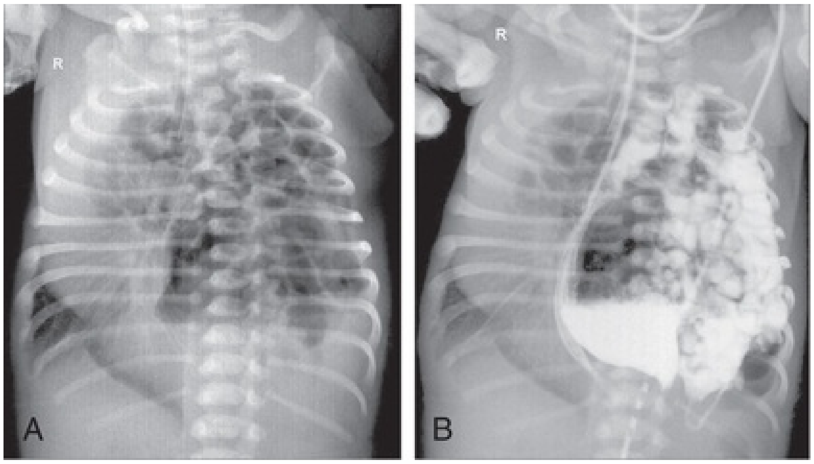

FIG. 122.11 **Bochdalek hernia. A, Chest radiograph showing herniated bowel loops in the left hemithorax, displacement of the mediastinum to the contralateral side, severely reduced lung space, and unclear lung fields bilaterally. B, Upper gastrointestinal tract radiograph showing the stomach and bowel loops stained with contrast in the left hemithorax. (From Hu X, Liu B: Bochdalek hernia, *Lancet* 392:60, 2018.)**

Arriving at the diagnosis early in pregnancy allows for prenatal counseling, possible fetal interventions, and planning for postnatal care. A referral to a center providing high-risk obstetrics, pediatric surgery, and tertiary care neonatology is advised. Careful evaluation for other anomalies should include echocardiography and amniocentesis. To avoid unnecessary pregnancy termination and unrealistic expectations, an experienced multidisciplinary group must carefully counsel the parents of a child diagnosed with a diaphragmatic hernia.

Respiratory distress is a cardinal sign in babies with CDH. It may occur immediately after birth, or there may be a “honeymoon” period of up to 48 hr during which the baby is relatively stable. Early respiratory distress, within 6 hr after birth, is thought to be a poor prognostic sign. Respiratory distress is characterized clinically by tachypnea, grunting, use of accessory muscles, and cyanosis. Children with CDH may also have a scaphoid abdomen and increased chest wall diameter. Bowel sounds may also be heard in the chest with decreased breath sounds bilaterally. The point of maximal cardiac impulse may be displaced away from the side of the hernia if mediastinal shift has occurred. A chest radiograph and passage of a nasal gastric tube are usually sufficient to confirm the diagnosis.

A small group of infants with CDH present beyond the neonatal period. Patients with a delayed presentation may experience vomiting as a result of intestinal obstruction or mild respiratory symptoms. Occasionally, incarceration of the intestine proceeds to ischemia with sepsis and shock. Unrecognized diaphragmatic hernia is a rare cause of sudden death in infants and toddlers. Group B streptococcal sepsis has been associated with delayed onset of symptoms and a CDH (often right side).

Treatment

Initial Management

Delivery at a tertiary center with experience in the management of CDH is required to provide early, appropriate respiratory support. In the delivery room, infants with respiratory distress should be rapidly stabilized with endotracheal intubation. *Prolonged mask ventilation in the delivery room, which enlarges the stomach and small bowel and thus makes oxygenation more difficult, must be avoided and a naso- or orogastric tube placed immediately for decompression.* Arterial (preductal and postductal) and central venous (umbilical) lines are mandated, as are a urinary catheter and nasogastric tube. A preductal arterial oxygen saturation (SpO_2) value ≥85% should be the minimum goal. Volutrauma is a significant problem. *Gentle ventilation with permissive hypercapnia* reduces lung injury, need for ECMO, and mortality. Factors that contribute to pulmonary hypertension (hypoxia, acidosis, hypothermia) should be avoided. Echocardiography is important to guide therapeutic decisions by measuring pulmonary and system vascular pressures and defining the presence of cardiac dysfunction. Routine use of inotropes is indicated in the presence of left ventricular dysfunction. Babies with CDH may be surfactant deficient. Although surfactant is frequently used, no study has proved that it is beneficial in treatment of CDH, and it may precipitate decompensation. In infants with severe respiratory failure and hypoxemia, sedation and paralysis may be required.

Ventilation Strategies

Conventional mechanical ventilation, high-frequency oscillatory ventilation (HFOV), and ECMO are the 3 main strategies to support respiratory failure in the newborn with CDH. The goal is to maintain oxygenation and CO_2 elimination without inducing volutrauma. Conventional ventilation using a gentle, lung protective strategy (PIP <25, PEEP 3-5 cm H_2O) that allows for permissive hypercapnia (PaCO_2 <65-70 mm Hg) is recommended. Permissive hypercapnia (as opposed to hyperventilation with high PIP) has reduced lung injury and improved survival. HFOV as a rescue therapy is indicated if a PIP

>25 is required to maintain appropriate ventilation or if hypoxemia persists.

Inhaled NO is a selective pulmonary vasodilator. Its use reduces ductal shunting and pulmonary pressures and results in improved oxygenation. Although iNO has been helpful in PPHN, randomized trials have not demonstrated improved survival or reduced need for ECMO when iNO is used in newborns with CDH. Nonetheless, iNO is used in patients with CDH as a bridge to ECMO.

Extracorporeal Membrane Oxygenation

The availability of ECMO and the utility of preoperative stabilization has improved survival of babies with CDH. ECMO is the therapeutic option for children in whom conventional ventilation or HFOV fails. ECMO is most often used before repair of the defect. Several objective criteria for ECMO have been developed. Birthweight and the 5 min Apgar score may be the best predictors of outcome in patients treated with ECMO. There is no strict lower weight limit for ECMO, but generally, vessels in infants <1,800-2,000 g are too small to cannulate.

The duration of ECMO for neonates with diaphragmatic hernia is longer (7-14 days) than for those with PPHN (persistent fetal circulation) or meconium aspiration and may last up to 2-4 wk. Timing of repair of the diaphragm while the infant receives ECMO is controversial; some experts prefer early repair to allow a greater duration of ECMO after the repair, whereas many defer repair until the infant has demonstrated the ability to tolerate weaning from ECMO. The recurrence of pulmonary hypertension is associated with high mortality and weaning from ECMO support should be cautious. If the patient cannot be weaned from ECMO after repair of CDH, options include discontinuing support and, in rare cases, lung transplantation.

Novel Strategies for Infants With Congenital Diaphragmatic Hernia

The most reliable prenatal predictors of outcome in children with CDH studied is fetal US. A prospective study of US at 24-26 wk compared fetal LHR with mortality. There were no survivors with LHR <1, but all babies with LHR >1.4 survived. A 2nd important consideration was the presence of liver in the thoracic cavity, which is a poor prognostic feature. Human studies have shown no benefit for in utero repair of CDH. In another single-center study, a late gestation (32-34 wk) fetal MRI-derived TLV >40 mL was associated with >90% survival and only 10% need for ECMO, while TLV <20 mL was associated with <35% survival and >85% need for ECMO.

Based on the observation that hydrostatic pressure exerted by fetal lung fluid plays a critical role in lung growth and maturity, a promising experimental therapy is **in utero tracheal occlusion** . Although initial studies in affected fetuses did not demonstrate success, emerging preliminary reports in those with severe CDH (LHR <1 and intrathoracic liver) suggest that fetoscopic tracheal occlusion is associated with significantly reduced mortality and need for ECMO (see Chapter 116).

Surgical Repair

The ideal time to repair the diaphragmatic defect is under debate. Most experts wait at least 48 hr after stabilization and resolution of the pulmonary hypertension. Good relative indicators of stability are the requirement for conventional ventilation only, a low peak inspiratory pressure, and FIO_2 <50. If the newborn is receiving ECMO, an ability to be weaned from this support should be a consideration before surgical repair. In some centers the repair is done with the cannulas in place; in other centers the cannulas are removed. A subcostal approach is most frequently used (Fig. 122.12). This allows for good visualization of the defect, and if the abdominal cavity cannot accommodate the herniated contents, a polymeric silicone (Silastic) patch can be placed. Both laparoscopic and thoracoscopic repairs have been reported, but these should be reserved for only the most stable infants.

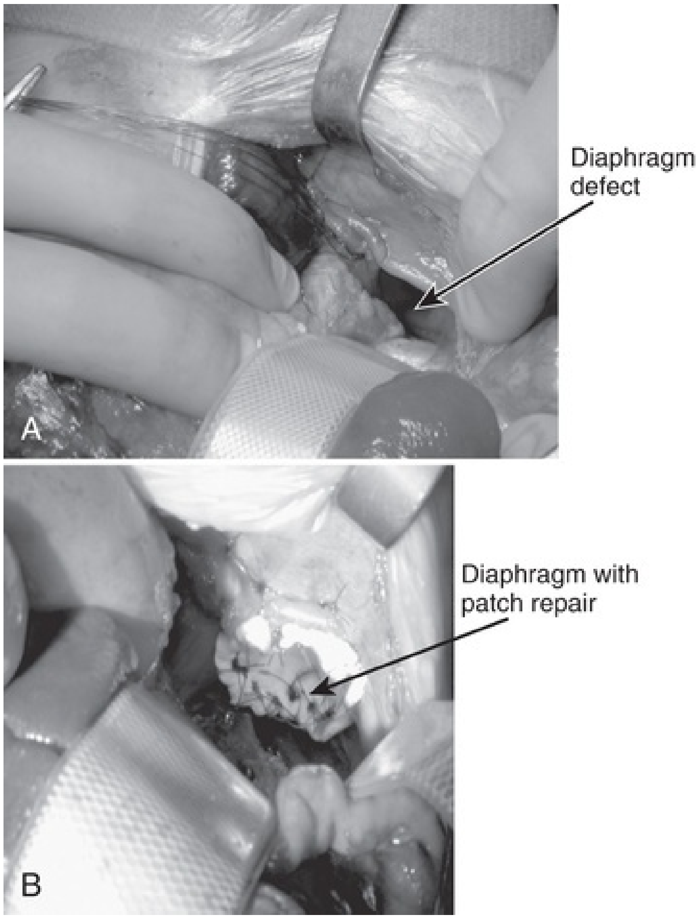

FIG. 122.12 **A,** Intraoperative photo of congenital diaphragmatic hernia (CDH) before repair. **B,** Intraoperative photo of patch repair of CDH.

The defect size and amount of native diaphragm present are variable. Whenever possible, a primary repair using native tissue is performed. If the defect is too large, a porous polytetrafluoroethylene (Gore-Tex) patch is used. There is a higher recurrence rate of CDH in children with patches (the patch does not grow as the child grows) than in those with native tissue repairs. A loosely fitted patch may reduce the recurrence rates.

Following surgical repair, the infant must be carefully monitored for worsening pulmonary hypertension. In some patients, a postoperative course of ECMO is needed. Other recognized complications include bleeding, chylothorax, and bowel obstruction.

Outcome and Long-Term Survival

Overall survival of liveborn infants with CDH is 71%. Relative predictors of a poor prognosis include an associated major anomaly, symptoms before 24 hr of age, severe pulmonary hypoplasia, herniation to the contralateral lung, and the need for ECMO. The size of the defect appears to be the strongest predictor of morbidity.

Pulmonary problems continue to be a source of morbidity for long-term survivors of CDH. Children receiving CDH repair who were studied at 6-11 yr of age demonstrated significant decreases in forced expiratory flow at 50% of vital capacity and decreased peak expiratory flow. Both obstructive and restrictive patterns can occur. Those without severe pulmonary hypertension and barotrauma do the best. Those at highest risk include children who required ECMO and patch repair, but the data clearly show that CDH survivors who did not require ECMO also need frequent attention to pulmonary issues. At discharge, up to 20% of infants require oxygen, but only 1–2% require oxygen past 1 yr old. BPD is frequently documented radiographically but will improve as more alveoli develop and the child ages.

Gastroesophageal reflux disease (GERD) is reported in >50% of children with CDH. GERD is more common in children whose diaphragmatic defect involves the esophageal hiatus. **Intestinal obstruction** is reported in up to 20% of children and may result from a midgut volvulus, adhesions, or a recurrent hernia that became incarcerated. **Recurrent diaphragmatic hernia** is reported in 5–20% in most series. Children with patch repairs are at highest risk.

Children with CDH typically have delayed growth in the 1st 2 yr of life. Contributing factors include poor intake, GERD, and a caloric requirement that may be higher because of the energy required to breathe. Many children normalize and “catch up” in growth by the time they are 2 yr old.

Neurocognitive defects are common and may result from the disease or the interventions. The incidence of neurologic abnormalities is higher in infants who require ECMO (67% vs 24% of those who do not). The abnormalities are similar to those seen in neonates treated with ECMO for other diagnoses and include transient and permanent developmental delay, abnormal hearing or vision, and seizures. Serious hearing loss may occur in up to 28% of children who underwent ECMO. The majority of neurologic abnormalities are classified as mild to moderate.

Other long-term problems include pectus excavatum and scoliosis. Survivors of CDH repair, particularly those requiring ECMO support, have a variety of long-term abnormalities that appear to improve with time but require close monitoring and multidisciplinary support.

122.11

Foramen of Morgagni Hernia

Shawn K. Ahlfeld

Failure of the sternal and crural portions of the diaphragm to meet and fuse produces the foramen of Morgagni hernia. These defects are usually small, with a greater transverse than anteroposterior diameter, and are more often right sided (90%) but may be bilateral. The transverse colon, small intestine, or liver is usually contained in the hernial sac. Most children with these defects are asymptomatic and are diagnosed beyond the neonatal period, often by chest radiograph performed for evaluation of another condition. The anterolateral radiograph shows a structure behind the heart, and a lateral film localizes the mass to the retrosternal area. Chest CT or MRI confirms the diagnosis. When symptoms occur, they can include recurrent respiratory infections, cough, vomiting, or reflux; in rare cases, incarceration may occur. Repair is recommended for all patients, in view of the risk of bowel strangulation, and can be accomplished laparoscopically. Prosthetic material is rarely required.

122.12

Paraesophageal Hernia

Shawn K. Ahlfeld

Paraesophageal hernia is differentiated from the hiatal hernia in that the gastroesophageal junction is in the normal location. The herniation of the stomach alongside or adjacent to the gastroesophageal junction is prone to incarceration with strangulation and perforation. A previous Nissen fundoplication and other diaphragmatic procedures are risk factors. This unusual diaphragmatic hernia should be repaired promptly after identification.

122.13

Eventration

Shawn K. Ahlfeld

Eventration of the diaphragm is an abnormal elevation consisting of a thinned diaphragmatic muscle that causes elevation of the entire hemidiaphragm or more often the anterior aspect of the hemidiaphragm. This elevation produces a paradoxical motion of the affected hemidiaphragm. Most eventrations are asymptomatic and do not require repair. A congenital form is the result of either incomplete development of the muscular portion or central tendon or abnormal development of the phrenic nerves. Congenital eventration may affect lung development, but it has not been associated with pulmonary hypoplasia. The differential diagnosis includes diaphragmatic paralysis, diaphragmatic hernia, traction injury, and iatrogenic injury after heart surgery. Eventration is also associated with pulmonary sequestration, congenital heart disease, spinal muscular atrophy with respiratory distress, and chromosomal trisomies. Most eventrations are asymptomatic and do not require repair. The indications for surgery include continued need for mechanical ventilation, recurrent infections, and failure to thrive. Large or symptomatic eventrations can be repaired by plication through an abdominal or thoracic approach that is minimally invasive.

Extrapulmonary Air Leaks: Pneumothorax, Pneumomediastinum, Pulmonary Interstitial Emphysema, Pneumopericardium

Shawn K. Ahlfeld

Keywords

pneumothorax
pneumomediastinum
pulmonary interstitial emphysema

- pneumopericardium
- pulmonary hypoplasia
- tension pneumothorax

Asymptomatic pneumothorax, usually unilateral, is estimated to occur in 1–2% of all newborn infants; symptomatic pneumothorax and pneumomediastinum are less common (see Chapter 113). The incidence of pneumothorax is increased in infants with lung diseases such as meconium aspiration and RDS; in those who receive assisted ventilation, especially if high-frequency ventilation (HFV) support is necessary; and in infants with urinary tract anomalies or oligohydramnios.

Etiology and Pathophysiology

The most common cause of pneumothorax is overdistention resulting in alveolar rupture. Alveolar overdistention can occur with positive pressure ventilation during neonatal resuscitation, or it may occur in association with the “ball-valve” phenomenon that results from aspiration (classically meconium) and bronchial/bronchiolar obstruction. Although **spontaneous rupture** of an underlying pulmonary malformation (e.g., lobar emphysema, congenital lung cyst, pneumatocele) occurs, it is usually in an otherwise normal lung, and no etiology is identified.

Pneumothorax associated with **pulmonary hypoplasia** is common, tends to occur during the 1st few hr after birth, and is caused by reduced alveolar surface area and poorly compliant lungs. It is associated with disorders of decreased amniotic fluid volume (Potter syndrome, renal agenesis, renal dysplasia, chronic amniotic fluid leak), decreased fetal breathing movement (oligohydramnios, neuromuscular disease), pulmonary space-occupying lesions (diaphragmatic hernia, pleural effusion, chylothorax), and thoracic abnormalities (thoracic dystrophies).

Gas from a ruptured alveolus escapes into the interstitial spaces of the lung, where it tracks along small conducting airways and dissects along the peribronchial and perivascular connective tissue sheaths to the hilum of the lung (pulmonary interstitial emphysema). If the volume of escaped air is great enough, it may collect in the mediastinal space (**pneumomediastinum**) or rupture into the pleural space (**pneumothorax**), subcutaneous tissue (**subcutaneous emphysema**), peritoneal cavity (**pneumoperitoneum**), and/or pericardial sac (**pneumopericardium**). Rarely, increased mediastinal pressure may compress the pulmonary veins at the hilum and thereby interfere with pulmonary venous return to the heart and cardiac output. On occasion, air may embolize into the circulation (pulmonary air embolism) and cause cutaneous blanching, air in intravascular catheters, an air-filled heart and vessels on chest radiographs, and death.

Tension pneumothorax occurs if an accumulation of air within the pleural space is sufficient to elevate intrapleural pressure above atmospheric pressure. Unilateral tension pneumothorax results in impaired ventilation not only in the ipsilateral lung but also in the contralateral lung because of a shift in the mediastinum toward the contralateral side. Compression of the vena cava and torsion of the great vessels may interfere with venous return.

Clinical Manifestations

The physical findings of a clinically asymptomatic pneumothorax are hyperresonance and diminished ipsilateral breath sounds with or without tachypnea. Symptomatic pneumothorax is characterized by respiratory distress, which varies from merely high respiratory rate to severe dyspnea, tachypnea, and cyanosis. Irritability and restlessness or apnea may be the earliest signs. The onset is usually sudden but may be gradual; an infant may rapidly become critically ill. Physical exam findings include chest asymmetry with an increased anteroposterior diameter, hyperresonance, and diminished or absent breath sounds. The heart is displaced toward the contralateral side, resulting in displacement of the cardiac apex and point of maximal impulse. The diaphragm is displaced downward, as is the liver with right-sided pneumothorax, and may result in abdominal distention. Because pneumothorax may be bilateral in approximately 10% of patients, symmetry of findings does not rule it out. In tension pneumothorax, signs of shock are typical.

Pneumomediastinum can occur in patients with pneumothorax and is usually asymptomatic. The degree of respiratory distress depends on the amount of trapped gas; if great, bulging of the midthoracic area is observed, the neck veins are distended, and blood pressure is low. The last 2 findings are a result of tamponade of the systemic and pulmonary veins. Although often asymptomatic, subcutaneous emphysema in newborn infants is almost pathognomonic of pneumomediastinum.

Pulmonary interstitial emphysema (PIE) may precede the development of a pneumothorax or may occur independently and lead to increasing respiratory distress as a result of decreased compliance, hypercapnia, and hypoxemia. Hypoxemia is caused by an increased $\mathrm{PA\text{-}aO}_2$ and intrapulmonary shunting. Progressive enlargement of blebs of gas may result in cystic dilation and respiratory deterioration resembling pneumothorax. In severe cases, pulmonary interstitial emphysema precedes the development of BPD. Avoidance of high inspiratory or mean airway pressures may prevent the development of pulmonary interstitial emphysema. Treatment may include bronchoscopy in patients with evidence of mucous plugging, selective intubation and ventilation of the uninvolved bronchus, oxygen, general respiratory care, and HFV.

Diagnosis

Pneumothorax and other air leaks should be suspected in newborn infants who show signs of respiratory distress, are restless or irritable, or have a sudden change in condition. The diagnosis of **pneumothorax** is established by chest radiography, with the edge of the collapsed lung standing out in relief against the pneumothorax (Fig. 122.13). **Pneumomediastinum** is signified by hyperlucency around the heart border and between the sternum and the heart border (Fig. 122.14). *Transillumination* of the thorax is often helpful in the emergency diagnosis of pneumothorax; the affected side transmits excessive light. Associated renal anomalies are identified by US. **Pulmonary hypoplasia** is suggested by signs of uterine compression (extremity contractures), a small thorax on chest radiographs, severe hypoxia with hypercapnia, and signs of the primary disease (hypotonia, diaphragmatic hernia, Potter syndrome).

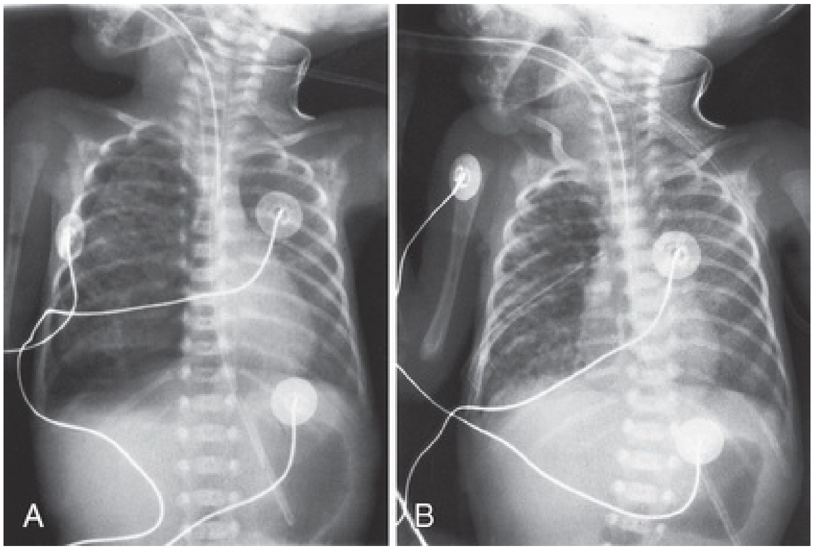

FIG. 122.13 **A,** Right-sided tension pneumothorax and widespread right lung pulmonary interstitial emphysema in a preterm infant receiving intensive care. **B,** Resolution of pneumothorax with a chest tube in place. Pulmonary interstitial emphysema (PIE) persists. (From Meerstadt PWD, Gyll C: *Manual of neonatal emergency x-ray interpretation,* Philadelphia, 1994, Saunders, p 73.)

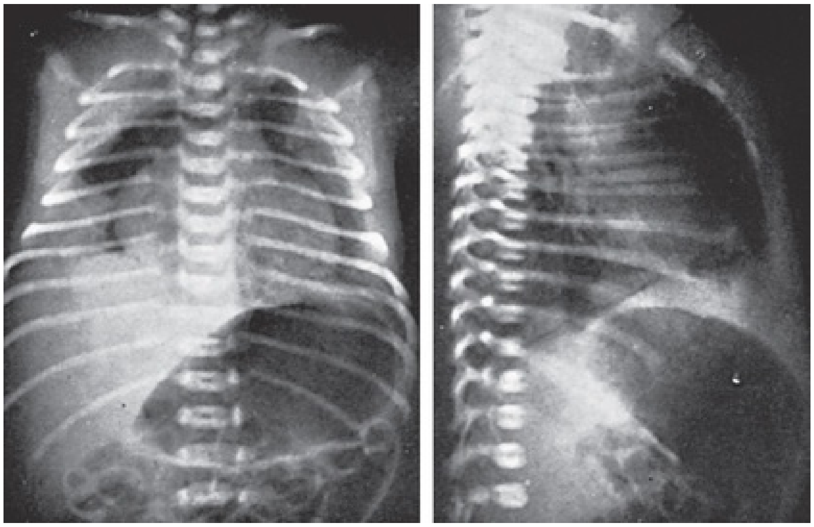

FIG. 122.14 **Pneumomediastinum in newborn infant. The anteroposterior view (*left*) demonstrates compression of the lungs, and the lateral view (*right*) shows bulging of the sternum, each resulting from distention of the mediastinum by trapped air.**

Pneumopericardium may be asymptomatic, requiring only general supportive treatment, but it usually manifests as sudden shock with tachycardia, muffled heart sounds, and poor pulses suggesting tamponade.

Pneumoperitoneum from air dissecting through the diaphragmatic apertures during mechanical ventilation may be confused with intestinal perforation. Abdominal paracentesis can be helpful in differentiating the 2 conditions. The presence of organisms on Gram stain of intestinal contents suggests the latter. Occasionally, pneumoperitoneum can result in an abdominal compartment syndrome requiring decompression.

Treatment

Without a continued air leak, asymptomatic and mildly symptomatic, small pneumothoraces require only close observation. Conservative management of a pneumothorax is effective even in selected infants requiring ventilatory support. Frequent small feedings may prevent gastric dilation and minimize crying, which can further compromise ventilation and worsen the pneumothorax. Breathing 100% oxygen in term infants may accelerate the resorption of free pleural air into blood by reducing the nitrogen tension in blood and producing a resultant nitrogen pressure gradient from the trapped gas in the blood; the clinical effectiveness is not proved, however, and the benefit must be weighed against the risks of O_2 toxicity. With severe respiratory or circulatory embarrassment, emergency decompression by *needle thoracentesis* using a soft, small catheter is indicated. Either immediately or after catheter aspiration, a **chest tube** should be inserted and attached to underwater seal drainage (see Fig. 122.13). If the air leak is ongoing, continuous suction (−5 to −20 cm H_2O) may be needed to evacuate the pneumothorax completely. A pneumopericardium requires prompt evacuation of entrapped air. Severe localized PIE may respond to selective bronchial intubation. Surfactant therapy for RDS reduces the incidence of pneumothorax.

Pulmonary Hemorrhage

Shawn K. Ahlfeld

Keywords

pulmonary hemorrhage
surfactant
excessive pulmonary blood flow
indomethacin
patent ductus arteriosus

Massive pulmonary hemorrhage is a relatively uncommon, but catastrophic complication with a high risk of morbidity and mortality. Some degree of pulmonary hemorrhage occurs in about 10% of extremely preterm infants. However, massive pulmonary hemorrhage is less common and can be fatal. Autopsy demonstrates massive pulmonary hemorrhage in 15% of neonates who die in the 1st 2 wk of life. The reported incidence at autopsy varies from 1-4 per 1,000 live births. Approximately 75% of affected patients weigh <2,500 g at birth. Prophylactic indomethacin in ELBW infants reduces the incidence of pulmonary hemorrhage.

Most infants with pulmonary hemorrhage have had symptoms of respiratory distress that are indistinguishable from those of RDS. The onset may occur at birth or may be delayed several days. **Hemorrhagic pulmonary edema** is the source of blood in many cases and is associated with significant ductal shunting and high pulmonary blood flow or severe left-sided heart failure resulting from hypoxia. In severe cases, sudden cardiovascular collapse, poor lung compliance, profound cyanosis, and hypercapnia may be present. Radiographic findings are varied and nonspecific, ranging from minor streaking or patchy infiltrates to massive consolidation.

The risk of pulmonary hemorrhage is increased in association with acute pulmonary infection, severe asphyxia, RDS, assisted ventilation, PDA, congenital heart disease, erythroblastosis fetalis, hemorrhagic disease of the newborn, thrombocytopenia, inborn errors of ammonia metabolism, and cold injury. Pulmonary hemorrhage is the only severe complication in which the rate is *increased* with surfactant treatment. Pulmonary hemorrhage is seen with all surfactants; the incidence ranges from 1–5% of treated infants and is higher with natural surfactant. Bleeding is predominantly alveolar in approximately 65% of cases and interstitial in the rest. Bleeding into other organs is observed at autopsy of severely ill neonates, suggesting an additional bleeding diathesis, such as disseminated intravascular coagulation. Acute pulmonary hemorrhage may rarely occur in previously healthy full-term infants. The cause is unknown. Pulmonary hemorrhage may manifest as hemoptysis or blood in the nasopharynx or airway with no evidence of upper respiratory or gastrointestinal bleeding. Patients present with acute, severe respiratory failure requiring mechanical ventilation. Chest radiographs usually demonstrate bilateral alveolar infiltrates. The condition usually responds to intensive supportive treatment (see Chapter 436).

Treatment of pulmonary hemorrhage includes blood replacement, suctioning to clear the airway, intratracheal administration of epinephrine, and tamponade with increased mean airway pressure (often requiring HFV). Although surfactant treatment has been associated with the development of pulmonary hemorrhage, administration of exogenous surfactant after the bleeding has occurred can improve lung compliance, because the presence of intraalveolar blood and protein can inactivate surfactant.

CHAPTER 123

Digestive System Disorders

123.1

Meconium Ileus, Peritonitis, and Intestinal Obstruction

Juan P. Gurria, Rebeccah L. Brown

Keywords

anorectal plugs
cystic fibrosis
Gastrografin enema
meconium ileus
meconium peritonitis
meconium plugs

Meconium consists of bile salts, bile acids, and debris shed from the intestinal mucosa in the intrauterine period. More than 90% of full-term newborn infants and 80% of very-low-birthweight (VLBW) infants pass meconium within the 1st 24 hr. The possibility of intestinal obstruction should be considered in any infant who does not pass meconium by 24-36 hr.

Meconium Plugs

Meconium plugs syndrome refers to intestinal obstruction, usually in the distal colon, rectum, and anal canal, caused by meconium plugs (Fig. 123.1). Resulting from a disproportionately low amount of water in the intestinal lumen, meconium plugs are a rare cause of intrauterine intestinal obstruction and meconium peritonitis unrelated to cystic fibrosis (CF). **Anorectal plugs** may also cause mucosal ulceration from bowel wall erosion and subsequent intestinal perforation. **Meconium plugs** are associated with small left colon syndrome in infants of diabetic mothers, CF (40%), Hirschsprung disease (40%), maternal opiate use, magnesium sulfate therapy for preeclampsia, and tocolysis. Up to 30% of patients can have spontaneous resolution. Initial treatment may include administration of a glycerin suppository or rectal irrigation with isotonic saline. In up to 95% of patients, a Gastrografin enema (meglumine diatrizoate, a hyperosmolar, water-soluble, radiopaque solution containing 0.1% polysorbate 80 [Tween 80] and 37% organically bound iodine) will be both diagnostic and therapeutic, inducing passage of the plug, presumably because the high osmolarity (1,900 mOsm/L) of the solution draws fluid rapidly into the intestinal lumen and loosens the inspissated material. Such rapid loss of fluid into the bowel may result in acute fluid shifts with dehydration and shock, so it is advisable to dilute the contrast material with an equal amount of water and provide intravenous (IV) fluids, during and for several hours after the procedure, sufficient to maintain normal vital signs, urine output, and electrolytes. After removal of a meconium plug, the infant should be observed closely and consideration given to performing diagnostic testing to identify **Hirschsprung disease** (congenital aganglionic megacolon; see Chapter 358.4) and CF (see Chapter 432).

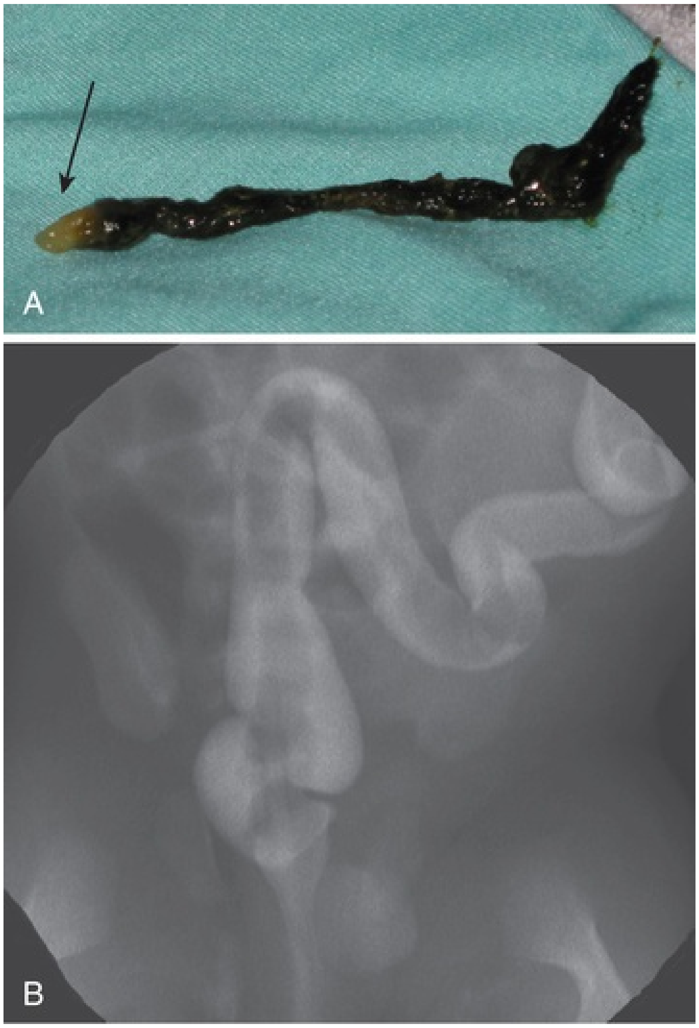

FIG. 123.1 **Meconium plug. A, Meconium plug evacuated after a diagnostic contrast enema demonstrated the distinctive white tip *(arrow)* . B, Image from a contrast enema in a term neonate with vomiting and bowel distension demonstrates the long filling defect characteristic of meconium plug syndrome. The child was relieved of the obstruction after evacuation of the plug, without recurrence of symptoms. (From Hernanz-Schulman M: Congenital and neonatal disorders. In Coley BD, editor: *Caffey's pediatric diagnostic imaging,* ed 12, Philadelphia, 2013, Elsevier, Fig 106-14.)**

Meconium Ileus

Meconium ileus, or impaction of inspissated meconium in the distal small bowel, accounts for up to 30% of cases of neonatal intestinal obstruction. It is common in patients with CF in whom the lack of fetal pancreatic enzymes inhibits digestive mechanisms, and meconium becomes viscid and mucilaginous. Clinically, neonates present with intestinal obstruction with or without perforation. Abdominal distention is prominent, and vomiting, often bilious, becomes persistent, although occasionally inspissated meconium stools may be passed shortly after birth. Meconium ileus can present as early as in utero, in which the fetus develops acute intestinal obstruction resulting in volvulus or perforation, peritoneal ascites, meconium peritonitis, and hydrops; if untreated, fetal loss may occur.

Meconium ileus is primarily associated with cystic fibrosis transmembrane regulator (CFTR) mutations F508del, G542X, W1282X, R553X, and G551D. Patients with two copies of the F508del mutation have a 25% chance of presenting with meconium ileus. F508del plus any other CF mutation confers 17% risk, and two other CF mutations confer a 12% risk of meconium ileus. In addition, non-CFTR genetic modifier genes influence meconium ileus. In families who already have at least one child with CF complicated by meconium ileus, there is a 39% risk for meconium ileus in subsequent children, which is more than the rates expected with autosomal recessive inheritance. In a twin study, 82% of monozygotic twins showed concordance for meconium ileus, whereas only 22% of dizygotic and 24% of two affected siblings showed concordance. Positive newborn screening for CF should prompt sweat testing when the infant weighs >2 kg and is at least 36 wk of corrected gestational age. Genetic testing confirms the diagnosis of CF (see Chapter 432).

The differential diagnosis involves other causes of intestinal obstruction, including intestinal pseudoobstruction, and other causes of pancreatic insufficiency (see Chapter 377). Prenatal diagnosis is readily achieved by ultrasound with identification of enlarged bowel loops or a mass with distention of the proximal small bowel. Clinically the diagnosis can be made with a history of CF in a sibling, by palpation of doughy or cordlike masses of intestines through the abdominal wall, and from the radiographic appearance. Plain radiographs reveal small bowel obstruction. Air-fluid levels may not be apparent because of the thickened meconium.

In contrast to the generally evenly distended intestinal loops above an atresia, the loops may vary in width and are not as evenly filled with gas. At points of heaviest meconium concentration, the infiltrated gas may create a bubbly, granular appearance (Figs. 123.2 and 123.3).

B

FIG. 123.2 Meconium ileus. A, Schematic drawing of uncomplicated meconium ileus. Pellets of inspissated meconium fill the terminal ileum proximal to a microcolon. Several loops of more proximal ileum contain thick, tenacious meconium. B, Enterotomy of proximal bowel and the nature of the thick and tenacious meconium. Note the dilated proximal loops of bowel filled with meconium and the progressively small caliber of the distal bowel leading to the microcolon. (A, From Leonidas JC, Berdon WE, et al: Meconium ileus and its complications: a reappraisal of plain film roentgen diagnostic criteria, *Am J Roentgenol Radium Ther Nucl Med* 108[3]:598–609, 1970; *B,* courtesy of Dr. Wallace W. Neblett III, Nashville, Ten)

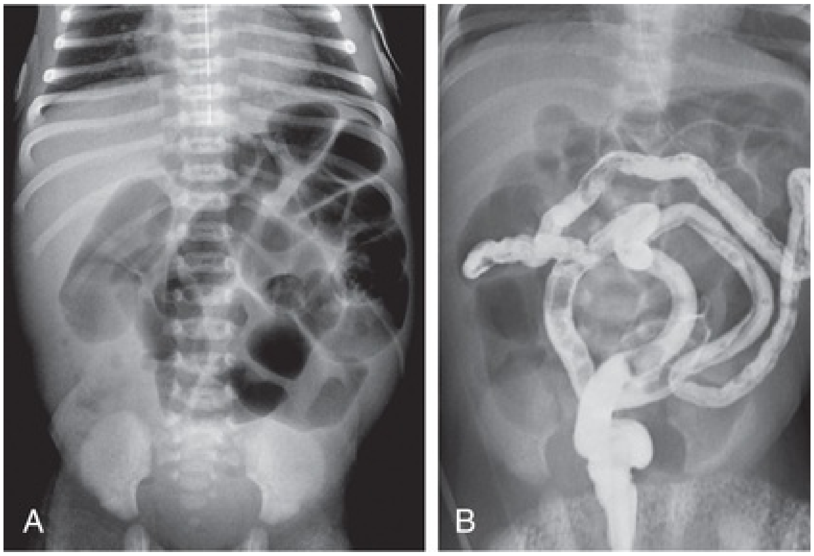

FIG. 123.3 **Uncomplicated meconium ileus. A, Abdominal radiograph in 3 day old infant with abdominal distention and bilious aspirates shows dilation of multiple loops of bowel. No calcifications are seen on the radiograph to suggest complicated meconium ileus. Orogastric tube near the gastroesophageal junction was subsequently advanced. B, Contrast enema demonstrates a microcolon, with multiple meconium plugs, consistent with the diagnosis of meconium ileus. (From Hernanz-Schulman M: Congenital and neonatal disorders. In Coley BD, editor: *Caffey's pediatric diagnostic imaging,* ed 13, Philadelphia, 2019, Elsevier, Fig 102-36).**

Treatment for simple meconium ileus is a high-osmolarity Gastrografin enema, as described for meconium plugs. If the procedure is unsuccessful or perforation of the bowel wall is suspected, a laparotomy is performed and the ileum opened at the point of largest diameter of the impaction. Approximately 50% of these infants have associated intestinal atresia, stenosis, or volvulus that requires surgery. The inspissated meconium is removed by gentle and patient irrigation with warm isotonic sodium chloride or *N* -acetylcysteine (Mucomyst) solution through a catheter passed between the impaction and the bowel wall. Some patients will require bowel resection with a temporary double-barrel enterostomy followed by serial irrigations and distal refeeding, or primary anastomosis at the initial operation. Most infants with meconium ileus survive the neonatal period. If meconium ileus is associated with CF, the long-term prognosis depends on the severity of the underlying disease (see Chapter 432).

Meconium Peritonitis

Perforation of the intestine may occur in utero or shortly after birth. Frequently, the intestinal perforation seals naturally with relatively little meconium leakage into the peritoneal cavity. Perforations occur most often as a complication of meconium ileus in infants with CF but occasionally result from a meconium plug or in utero intestinal obstruction of another cause.

Cases at the most severe end of the spectrum may be diagnosed on prenatal ultrasound with fetal ascites, polyhydramnios, bowel dilation, intraabdominal calcifications, and hydrops fetalis (Fig. 123.4). At the other end are cases in which an intestinal perforation may seal spontaneously and patients remain asymptomatic, except when meconium becomes calcified and is later discovered on radiographs. Alternatively, the clinical picture may be dominated by signs of intestinal obstruction (as in meconium ileus) with abdominal distention, vomiting, and absence of stools or chemical peritonitis presenting with sepsis. Treatment consists primarily of elimination of the intestinal obstruction and drainage of the peritoneal cavity with a timely surgical intervention proved to result in high survival rate and favorable outcome even in complicated meconium peritonitis.

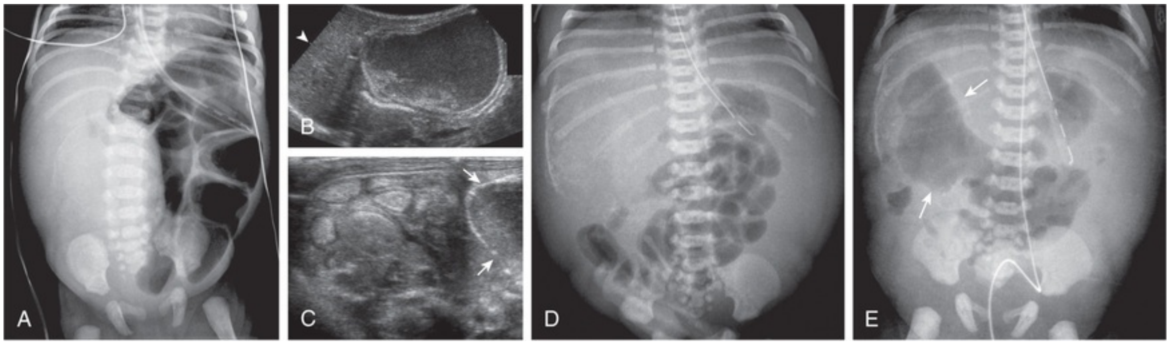

FIG. 123.4 Complicated meconium ileus. A, Abdominal radiograph in 2 day old girl with abdominal distention and bilious aspirates shows absence of bowel gas in the right abdomen with a partly calcified mass displacing gas-filled dilated loops of bowel to the left. B, Ultrasound image demonstrates the subhepatic, partly calcified mass with internal debris and fluid-fluid level. C, Additional ultrasound image shows a portion of the cyst wall *(arrows)* and multiple, abnormal, hyperechoic loops of bowel. D, Abdominal radiograph in different 1 day old infant shows a calcified mass in right upper quadrant, shown at sonography to represent a loculated complex meconium collection. E, Radiograph a few hours later of the same infant shown in D shows a persistent perforation with gas entering into the right upper quadrant collection. (From Hernanz-Schulman M: Congenital and neonatal disorders. In Coley BD, editor: *Caffey's pediatric diagnostic imaging,* ed 13, Philadelphia, 2019, Elsevier, Fig 102-37).

123.2

Necrotizing Enterocolitis

Rebeccah L. Brown

Keywords

biomarkers
necrotizing enterocolitis
NEC
pneumatosis intestinalis
primary peritoneal drainage
PPD
probiotics

Necrotizing enterocolitis (NEC) is the most common life-threatening emergency of the gastrointestinal (GI) tract in the newborn period. The disease is characterized by various degrees of mucosal or transmural necrosis of the intestine. The cause of NEC remains unclear but is most likely multifactorial. The incidence of NEC is 5–10% among infants with birthweight <1500 g, with mortality rates of 20–30% and approaching 50% in infants who require surgery. Both incidence and case fatality rates increase with decreasing birthweight and gestational age.

Pathology and Pathogenesis

Many factors contribute to the development of the pathologic findings of NEC, including mucosal ischemia and subsequent necrosis, gas accumulation in the submucosa of the bowel wall (pneumatosis intestinalis), and progression of the necrosis to perforation, peritonitis, sepsis, and death. The distal part of the ileum and the proximal segment of colon are involved most frequently; in fatal cases, gangrene may extend from the stomach to the rectum (NEC totalis). The pathogenesis of NEC remains to be completely elucidated, but 3 major risk factors have been implicated: prematurity, bacterial colonization of the gut, and formula feeding. NEC develops primarily in premature infants with exposure to metabolic substrate in the context of immature intestinal immunity, microbial dysbiosis, and mucosal ischemia. An underlying genetic predisposition is being recognized with variants in genes regulating immunomodulation and inflammation (e.g., Toll-like receptor-4, IL-6), apoptosis and cellular repair (e.g., platelet-activating factor), and oxidant stress (e.g., vascular endothelial growth factor, arginine, nitric oxide). *The greatest risk factor for NEC is prematurity.*

NEC rarely occurs before the initiation of enteral feeding and is much less common in infants fed human milk. Aggressive enteral feeding may predispose to the development of NEC.

Although nearly 90% of all cases of NEC occur in preterm infants, the disease can occur in full-term neonates. NEC in term infants is often a secondary disease, seen more frequently in infants with history of birth asphyxia, Down syndrome, congenital heart disease, rotavirus infections, gastroschisis, and Hirschsprung disease.

Clinical Manifestations

Infants with NEC have a variety of signs and symptoms and may have an insidious or sudden catastrophic onset (Table 123.1). The onset of NEC is usually in the 2nd or 3rd week of life but can be as late as 3 mo in VLBW infants. Age of onset is inversely related to gestational age. The first signs of impending disease may be nonspecific, including lethargy and temperature instability, or related to GI pathology, such as abdominal distention, feeding intolerance, and bloody stools. Because of nonspecific signs, sepsis may be suspected before NEC. The spectrum of illness is broad, ranging from mild disease with only guaiac-positive stools to severe illness with bowel perforation, peritonitis, systemic inflammatory response syndrome, shock, and death. Laboratory derangements may include neutropenia, anemia, thrombocytopenia, coagulopathy, and metabolic acidosis. Hypotension and respiratory failure are common. Progression may be rapid, but it is unusual for the disease to progress from mild to severe after 72 hr.

From Kanto WP Jr, Hunter JE, Stoll BJ: Recognition and medical management of necrotizing enterocolitis, *Clin Perinatol* 21:335–346, 1994.

Diagnosis

A very high index of suspicion in treating preterm at-risk infants is crucial. Plain abdominal radiographs are essential to make a diagnosis of NEC. The finding of **pneumatosis intestinalis** (air in the bowel wall) confirms the clinical suspicion of NEC and is diagnostic; 50–75% of patients have pneumatosis when treatment is started (Fig. 123.5). Portal venous gas is a sign of severe disease, and **pneumoperitoneum** indicates a perforation (Figs. 123.6 and 123.7). Ultrasound with Doppler flow assessment may be useful to evaluate for free fluid, abscess, and bowel wall thickness, peristalsis, and perfusion.

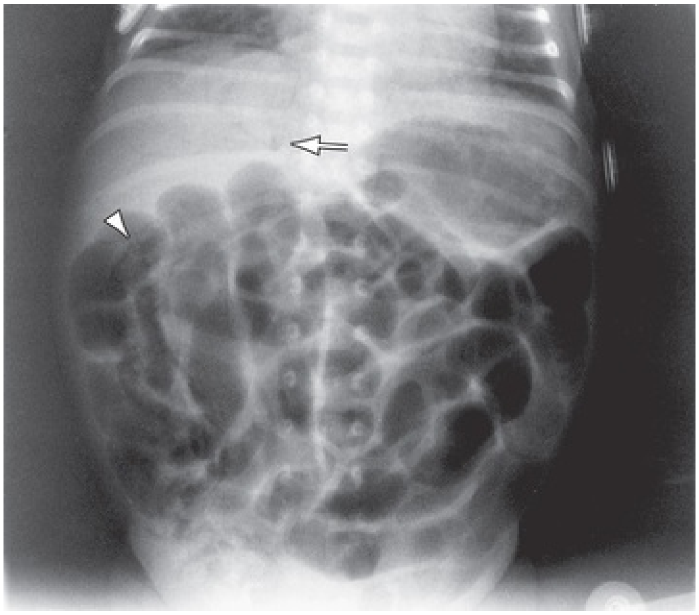

FIG. 123.5 Necrotizing enterocolitis (NEC). Kidney-ureter-bladder film demonstrates abdominal distention, hepatic portal venous gas *(arrow),* and a bubbly appearance of pneumatosis intestinalis (*arrowhead;* right lower quadrant). The latter 2 signs are thought to be pathognomonic for neonatal NEC.

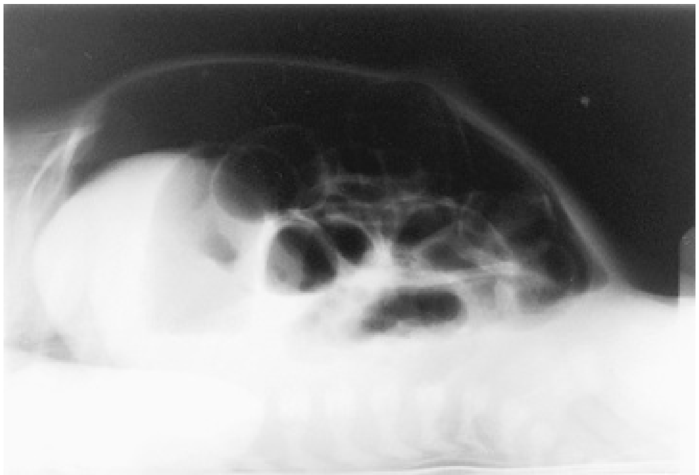

FIG. 123.6 Intestinal perforation. Cross-table abdominal radiograph in patient with neonatal NEC demonstrates marked distention and massive pneumoperitoneum, as evidenced by the free air below the anterior abdominal wall.

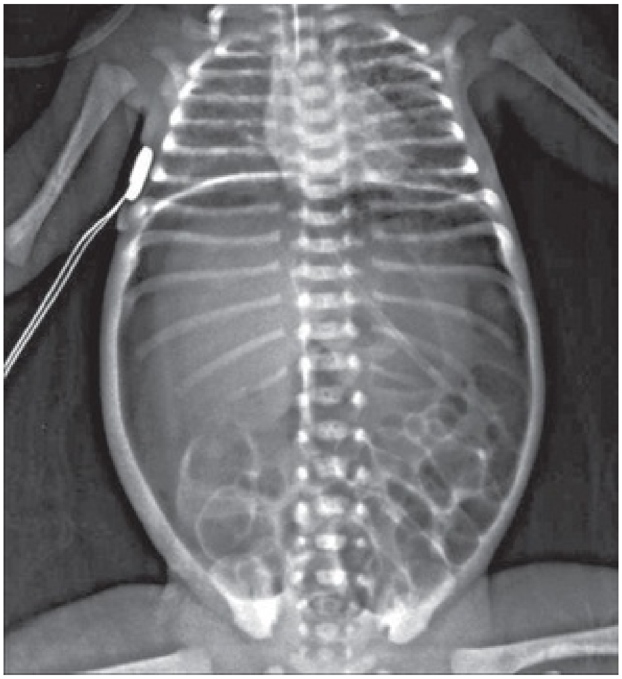

FIG. 123.7 Necrotizing enterocolitis (NEC). Plain abdominal x-ray film of an infant with

perforated NEC showing pneumoperitoneum. (From Tam PKH, Chung PHY, St Peter SD, et al: Advances in paediatric gastroenterology. *Lancet* 390:1072–1082, 2017, Fig 4).

The differential diagnosis of NEC includes specific infections (systemic or intestinal), GI obstruction, volvulus, and isolated intestinal perforation. **Idiopathic focal intestinal perforation** can occur spontaneously or after the early use of postnatal corticosteroids and indomethacin. Pneumoperitoneum develops in such patients, but they are usually less ill than those with NEC.

Treatment

Rapid initiation of therapy is required for infants with suspected as well as proven NEC. There is no definitive treatment for established NEC, so therapy is directed at providing supportive care and preventing further injury with cessation of feeding, nasogastric decompression, and administration of IV fluids. Careful attention to respiratory status, coagulation profile, and acid-base and electrolyte balances are important. Once blood has been drawn for culture, systemic antibiotics (with broad coverage based on the antibiotic sensitivity patterns of the gram-positive, gram-negative, and anaerobic organisms in the particular neonatal ICU) should be started immediately. If present, umbilical catheters should be removed, but good IV access needs to be maintained. Ventilation should be assisted in the presence of apnea or if abdominal distention is contributing to hypoxia and hypercapnia. Intravascular volume replacement with crystalloid or blood products, cardiovascular support with fluid boluses and/or inotropes, and correction of hematologic, metabolic, and electrolyte abnormalities are essential to stabilize the infant with NEC.

The patient's course should be monitored closely by means of frequent physical assessments; sequential anteroposterior and cross-table lateral or lateral decubitus abdominal radiographs to detect intestinal perforation; and serial determinations of hematologic, electrolyte, and acid-base status. Gown and glove isolation and grouping of infants at similar increased risks into cohorts separate from other infants should be instituted to contain an epidemic.

A surgeon should be consulted early in the course of treatment. The only absolute indication for surgery is evidence of perforation on abdominal radiograph (pneumoperitoneum) present in less than half of infants with perforation or necrosis at operative exploration. Progressive clinical deterioration despite maximum medical management, a single fixed bowel loop on serial radiographs, and abdominal wall erythema are relative indications for exploratory laparotomy. Ideally, surgery should be performed after intestinal necrosis develops but before perforation and peritonitis occur. The optimal surgical approach, however, remains controversial. The options for surgical treatment include **primary peritoneal drainage (PPD)** or exploratory laparotomy with resection of the necrotic intestine and usually stoma creation. Two randomized clinical trials in the mid-2000s comparing these approaches failed to demonstrate significant differences in survival, nutritional outcomes, or length of stay. A Cochrane analysis combining the results of both trials concluded that there were no significant benefits or harms of PPD over exploratory laparotomy. A 3rd randomized clinical trial (Necrotizing Enterocolitis Surgery Trial, NCT01029353) compares the 2 surgical approaches, with the primary outcome being death or neurodevelopmental outcomes at 18-22 mo adjusted age. A large, multicenter cohort study of 8,935 patients demonstrated that laparotomy was the initial therapy in two thirds of VLBW infants with surgical NEC, even in those <1,000 g. Mortality was about 30% in both the laparotomy group and the PPD-converted-to-laparotomy group (46% of PPD group eventually required laparotomy). PPD was found to be an independent risk factor for death (50% mortality), likely from its preferential use in the more seriously ill, unstable patients; however, 27% of patients undergoing PPD survived without further surgery. *The surgical approach depends on surgeon preference and physiologic status of the patient.*

Prognosis

Medical management fails in approximately 20–40% of patients with pneumatosis intestinalis at diagnosis; of these, 20–50% die. Early postoperative complications include wound infection, dehiscence, and stomal problems (prolapse, necrosis). Later complications include **intestinal strictures** , which occur in approximately 10% of surgically or medically managed patients. After massive intestinal resection, complications from postoperative NEC include **short bowel syndrome** (malabsorption, growth failure, malnutrition), complications related to central venous catheters (sepsis, thrombosis), and cholestatic jaundice. Preterm infants with NEC who require surgical intervention are at increased risk for adverse growth and neurodevelopmental outcomes.

Prevention

The most effective preventive strategy for NEC is the use of **human milk** . It is well documented that newborns exclusively breastfed have a reduced risk of NEC. However, because human milk does not provide complete nutritional support, fortification is essential for preterm infants. Some studies have suggested that an “exclusive human milk diet” using human rather than bovine fortifiers may further reduce the risk of NEC. Despite concerns about increased risk of NEC with early and aggressive feeding regimens in VLBW infants, a safe protocol remains unknown. While extensive data and meta-analyses would support the use of **probiotics** to prevent NEC, there is no clear consensus on the safest, most effective formulation, timing of administration, or length of therapy. Other preventive strategies using **prebiotics** and **synbiotics** have also been studied, with variable outcomes. Inhibitors of gastric acid secretion (H_2 -receptor blockers, proton pump inhibitors) or prolonged empirical antibiotics in the early neonatal period have been associated with increased risk of NEC and should be avoided.

Because early detection and treatment may prevent late deleterious consequences of NEC, considerable research is focused on identification of **biomarkers** for early identification of NEC, including C-reactive protein (CRP), urinary intestinal fatty acid–binding protein (I-FABP), claudin-3 (a tight junction protein), fecal calprotectin, acylcarnitine, IL-6, IL-8, and the heart rate characteristics (HRC) index. Near-infrared spectroscopy (NIRS) may be a promising predictive diagnostic modality for NEC.

123.3

Jaundice and Hyperbilirubinemia in the Newborn

Erin E. Shaughnessy, Neera K. Goyal

Keywords

- breast milk jaundice
- breastfeeding jaundice
- Crigler-Najjar syndrome
- hyperbilirubinemia
- jaundice
- kernicterus
- physiologic jaundice
- unconjugated hyperbilirubinemia

Hyperbilirubinemia is a common and, in most cases, benign problem in neonates. **Jaundice** is observed during the 1st wk after birth in approximately 60% of term infants and 80% of preterm infants. The yellow color usually results from the accumulation of unconjugated, nonpolar, lipid-soluble bilirubin pigment in the skin. This unconjugated bilirubin (designated **indirect-acting** by nature of the van den Bergh reaction) is an end product of heme-protein catabolism from a series of enzymatic reactions by heme-oxygenase and biliverdin reductase and nonenzymatic reducing agents in the reticuloendothelial cells. It may also be partly caused by deposition of pigment from conjugated bilirubin, the end product from indirect, unconjugated bilirubin that has undergone conjugation in the liver cell microsome by the enzyme uridine diphosphoglucuronic acid (UDP)–glucuronyl transferase to form the polar, water-soluble glucuronide of bilirubin **(direct-reacting).** Although bilirubin may have a physiologic role as an antioxidant, elevations of indirect, unconjugated bilirubin are potentially neurotoxic. Even though the conjugated form is not neurotoxic, direct hyperbilirubinemia indicates potentially serious hepatic disorders or a systemic illness.

Etiology

During the neonatal period, metabolism of bilirubin is in transition from the *fetal* *stage,* during which the placenta is the principal route of elimination of the lipid-soluble, unconjugated bilirubin, to the *adult stage,* during which the water-soluble conjugated form is excreted from hepatic cells into the biliary system and gastrointestinal tract. **Unconjugated hyperbilirubinemia** may be caused or increased by any factor that (a) increases the load of bilirubin to be metabolized by the liver (hemolytic anemias, polycythemia, bruising or internal hemorrhage, shortened red blood cell [RBC] life as a result of immaturity or transfusion of cells, increased enterohepatic circulation, infection); (b) damages or reduces the activity of the transferase enzyme or other related enzymes (genetic deficiency, hypoxia, infection, thyroid deficiency); (c) competes for or blocks the transferase enzyme (drugs and other substances requiring glucuronic acid conjugation); or (d) leads to an absence or decreased amounts of the enzyme or to reduction of bilirubin uptake by liver cells (genetic defect, prematurity). Gene polymorphisms in the hepatic uridine diphosphate glucuronosyltransferase isoenzyme 1A1 (*UGT1A1*) and the solute carrier organic anion transporter 1B1 (*SLCO1B1*), alone or in combination, influence the incidence of neonatal hyperbilirubinemia.

The toxic effects of elevated serum concentrations of unconjugated bilirubin are increased by factors that reduce the retention of bilirubin in the circulation (hypoproteinemia, displacement of bilirubin from its binding sites on albumin by competitive binding of drugs such as sulfisoxazole and moxalactam, acidosis, and increased free fatty acid concentration secondary to hypoglycemia, starvation, or hypothermia). Neurotoxic effects are directly related not only to the permeability of the blood-brain barrier and nerve cell membranes but also to neuronal susceptibility to injury, all of which are adversely influenced by asphyxia, prematurity, hyperosmolality, and infection. Early and frequent feeding decreases, whereas breastfeeding and dehydration increase, serum levels of bilirubin. Delay in passage of meconium, which contains 1 mg bilirubin/dL, may contribute to jaundice by enterohepatic recirculation after deconjugation by intestinal glucuronidase (Fig. 123.8). Drugs such as oxytocin (in the mother) and chemicals used in the nursery such as phenolic detergents may also produce unconjugated hyperbilirubinemia.

FIG. 123.8 Metabolism of bilirubin in the neonatal period. Neonatal production rate of bilirubin is 6-8 mg/kg/24 hr (in contrast to 3-4 mg/kg/24 hr in adults). Water-insoluble bilirubin is bound to albumin. At the plasma-hepatocyte interface, a liver membrane carrier (bilitranslocase) transports bilirubin to a cytosolic binding protein (ligandin or Y protein, now known to be glutathione *S* -transferase), which prevents back-absorption to plasma. Bilirubin is converted to bilirubin monoglucuronide (BMG). Neonates excrete more BMG than adults. In the fetus, conjugated lipid-insoluble BMG and bilirubin diglucuronide (BDG) must be deconjugated by tissue β-glucuronidases to facilitate placental transfer of lipid-soluble unconjugated bilirubin across the placental lipid membranes. After birth, intestinal or milk-containing glucuronidases contribute to the enterohepatic recirculation of bilirubin and possibly to the development of hyperbilirubinemia.

Clinical Manifestations

Jaundice usually appears during the early neonatal period, depending on etiology. Whereas jaundice from deposition of indirect bilirubin in the skin tends to appear bright yellow or orange, jaundice of the obstructive type (direct bilirubin) has a greenish or muddy yellow cast. Jaundice usually becomes apparent in a cephalocaudal progression, starting on the face and progressing to the abdomen and then the feet, as serum levels increase. Dermal pressure may reveal the anatomic progression of jaundice (face, approximately 5 mg/dL; mid-abdomen, 15 mg/dL; soles, 20 mg/dL), but clinical examination cannot reliably estimate serum levels. Noninvasive techniques for transcutaneous measurement of bilirubin that correlate with serum levels may be used to *screen* infants, but determination of serum bilirubin level is indicated in patients with elevated age-specific transcutaneous bilirubin measurement, progressing jaundice, or risk for hemolysis or sepsis. Infants with severe hyperbilirubinemia may present with lethargy and poor feeding and, without treatment, can progress to acute bilirubin encephalopathy (kernicterus) (see Chapter 123.4).

Differential Diagnosis

The distinction between *physiologic* and *pathologic* jaundice relates to the timing, rate of rise, and extent of hyperbilirubinemia, because some of the same causes of physiologic jaundice (e.g., large RBC mass, decreased capacity for bilirubin conjugation, increased enterohepatic circulation) can also result in pathologic jaundice. Evaluation should be determined on the basis of risk factors, clinical appearance, and severity of the hyperbilirubinemia (Tables 123.2 to 123.4). Jaundice that is present at birth or appears within the 1st 24 hr after birth should be considered **pathologic** and requires immediate attention. Potential diagnoses would include erythroblastosis fetalis, concealed hemorrhage, sepsis, or congenital infections, including syphilis, cytomegalovirus (CMV), rubella, and toxoplasmosis. Hemolysis is suggested by a rapid rise in serum bilirubin concentration (>0.5 mg/dL/hr), anemia, pallor, reticulocytosis, hepatosplenomegaly, and a positive family history. An unusually high proportion of direct-reacting bilirubin may characterize jaundice in infants who have received intrauterine transfusions for erythroblastosis fetalis. Jaundice that first appears on the 2nd or 3rd day is usually **physiologic** but may represent a more severe form. Familial nonhemolytic icterus (**Crigler-Najjar syndrome**) and early-onset breastfeeding jaundice are seen initially on the 2nd or 3rd day. Jaundice appearing after the 3rd day and within the 1st week suggests bacterial sepsis or urinary tract infection; it may also be caused by other infections, notably syphilis, toxoplasmosis, CMV, and enterovirus. Jaundice secondary to extensive ecchymosis or blood extravasation may occur during the 1st day or later, especially in premature infants. Polycythemia may also lead to early jaundice.

Table 123.2

Risk Factors for Development of Severe Hyperbilirubinemia*

MAJOR RISK FACTORS
Predischarge TSB or TcB level in the high-risk zone (see Fig. 123.10) Jaundice observed in the 1st 24 hr Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (G6PD deficiency), elevated end-tidal CO concentration Gestational age 35-36 wk Previous sibling received phototherapy Cephalohematoma or significant bruising Exclusive breastfeeding, particularly if nursing is not going well and weight loss is excessive East Asian race [†]
MINOR RISK FACTORS
Predischarge TSB or TcB level in the high intermediate-risk zone Gestational age 37-38 wk Jaundice observed before discharge Previous sibling with jaundice Macrosomic infant of a diabetic mother Maternal age ≥25 yr Male gender
DECREASED RISK [‡]
TSB or TcB level in the low-risk zone (see Fig. 123.10) Gestational age ≥41 wk Exclusive bottle feeding Black race Discharge from hospital after 72 hr

[*] In infants ≥35 wk of gestation; factors in approximate order of importance.

[†] Race as defined by mother's description.

[‡] These factors are associated with decreased risk of significant jaundice, listed in order of decreasing importance.

G6PD, Glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin; TSB, total serum bilirubin.

Adapted from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297–316, 2004.

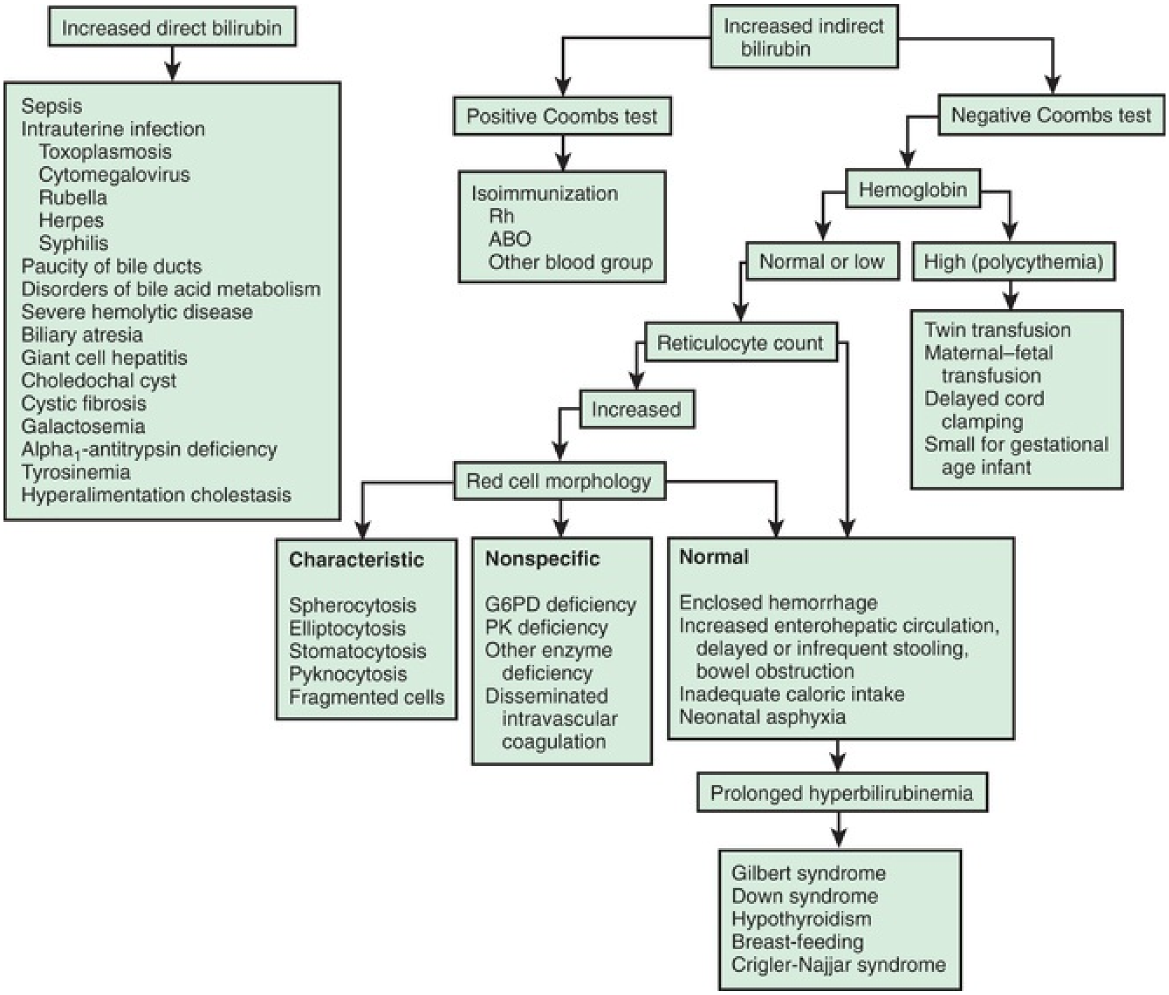
From Brown AK: Neonatal jaundice, *Pediatr Clin North Am* 9:575–603, 1962.

There is a long differential diagnosis for jaundice first recognized *after* the 1st week of life, including breast milk jaundice, septicemia, congenital atresia or paucity of the bile ducts, hepatitis, galactosemia, hypothyroidism, CF, and congenital hemolytic anemia crises related to RBC morphology and enzyme deficiencies (Fig. 123.9). The differential diagnosis for persistent jaundice during the 1st mo of life includes hyperalimentation-associated cholestasis, hepatitis, cytomegalic inclusion disease, syphilis, toxoplasmosis, familial nonhemolytic icterus, congenital atresia of the bile ducts, galactosemia, and inspissated bile syndrome following hemolytic disease of the newborn. Rarely, physiologic jaundice may be prolonged for several weeks, as in infants with hypothyroidism or pyloric stenosis.



Increased direct bilirubin
Sepsis
Intrauterine infection
Toxoplasmosis
Cytomegalovirus
Rubella
Herpes
Syphilis
Paucity of bile ducts
Disorders of bile acid metabolism
Severe hemolytic disease
Biliary atresia
Giant cell hepatitis
Choledochal cyst
Cystic fibrosis
Galactosemia
Alpha$_1$-antitrypsin deficiency
Tyrosinemia
Hyperalimentation cholestasis
Increased indirect bilirubin
Positive Coombs test
Isoimmunization
Rh
ABO
Other blood group
Negative Coombs test
Hemoglobin
Normal or low
High (polycythemia)
Twin transfusion
Maternal–fetal transfusion
Delayed cord clamping
Small for gestational age infant
Reticulocyte count
Increased
Red cell morphology
Characteristic
Spherocytosis
Elliptocytosis
Stomatocytosis
Pyknocytosis
Fragmented cells
Nonspecific
G6PD deficiency
PK deficiency
Other enzyme deficiency
Disseminated intravascular coagulation
Normal
Enclosed hemorrhage
Increased enterohepatic circulation, delayed or infrequent stooling, bowel obstruction
Inadequate caloric intake
Neonatal asphyxia
Prolonged hyperbilirubinemia
Gilbert syndrome
Down syndrome
Hypothyroidism
Breast-feeding
Crigler-Najjar syndrome

FIG. 123.9 **Schematic approach to the diagnosis of neonatal jaundice. G6PD, Glucose-6-phosphate dehydrogenase; PK, pyruvate kinase. (From Oski FA: Differential diagnosis of jaundice. In Taeusch HW, Ballard RA, Avery MA, editors: *Schaffer and Avery's diseases of the newborn,* ed 6, Philadelphia, 1991, Saunders.)**

Regardless of gestation or time of appearance of jaundice, patients with *significant* hyperbilirubinemia *and* those with symptoms or signs require a complete diagnostic evaluation, which includes determination of direct and indirect bilirubin fractions, hemoglobin, reticulocyte count, blood type, Coombs test, and examination of a peripheral blood smear. Indirect hyperbilirubinemia, reticulocytosis, and a smear with evidence of RBC destruction suggest hemolysis (see Table 123.3). In the absence of blood group incompatibility, non–immunologically induced hemolysis should be considered. If the reticulocyte count, Coombs test result, and direct bilirubin value are normal, physiologic or pathologic indirect hyperbilirubinemia may be present (see Fig. 123.9). If direct hyperbilirubinemia is present, diagnostic possibilities include hepatitis, congenital bile duct disorders (biliary atresia, paucity of bile ducts, Byler disease), cholestasis, inborn errors of metabolism, CF, congenital hemosiderosis, and sepsis.

Physiologic Jaundice (Icterus Neonatorum)

Under normal circumstances, the level of indirect bilirubin in umbilical cord serum is 1-3 mg/dL and rises at a rate of <5 mg/dL/24 hr; thus, jaundice becomes visible on the 2nd or 3rd day, usually peaking between the 2nd and 4th days at 5-6 mg/dL and decreasing to <2 mg/dL between the 5th and 7th days after birth. Jaundice associated with these changes is designated *physiologic* and is believed to be the result of increased bilirubin production from the breakdown of fetal RBCs combined with transient limitation in the conjugation of bilirubin by the immature neonatal liver.

Overall, 6–7% of full-term infants have indirect bilirubin levels >13 mg/dL, and <3% have levels >15 mg/dL. Risk factors for elevated indirect bilirubin include maternal age, race (Chinese, Japanese, Korean, Native American), maternal diabetes, prematurity, drugs (vitamin K_3 , novobiocin), altitude, polycythemia, male sex, trisomy 21, cutaneous bruising, blood extravasation (cephalohematoma), oxytocin induction, breastfeeding, weight loss (dehydration or caloric deprivation), delayed bowel movement, and a family history of, or a sibling who had, physiologic jaundice (see Table 123.2). In infants without these variables, indirect bilirubin levels rarely rise >12 mg/dL, whereas infants with several risk factors are more likely to have higher bilirubin levels. A combination of breastfeeding, variant-glucuronosyltransferase activity (1A1), and alterations of the organic anion transporter-2 gene increases the risk of hyperbilirubinemia. Predicting which neonates are at risk for exaggerated physiologic jaundice can be based on *hour-specific* bilirubin levels in the 1st 24-72 hr of life (Fig. 123.10). Transcutaneous measurements of bilirubin are linearly correlated with serum levels and can be used for screening. Indirect bilirubin levels in full-term infants decline to adult levels (1 mg/dL) by 10-14 days of life. Persistent indirect hyperbilirubinemia beyond 2 wk suggests hemolysis, hereditary glucuronyl transferase deficiency, breast milk jaundice, hypothyroidism, or intestinal obstruction. Jaundice associated with pyloric stenosis may be the result of caloric deprivation, relative deficiency of hepatic UDP–glucuronyltransferase, or an increase in the enterohepatic circulation of bilirubin from the ileus. In premature infants, the rise in serum bilirubin tends to be the same or somewhat slower but of longer duration than in term infants. Peak levels of 8-12 mg/dL are not usually reached until the 4th-7th day, and jaundice is infrequently observed after the 10th day, corresponding to the maturation of mechanisms for bilirubin metabolism and excretion.

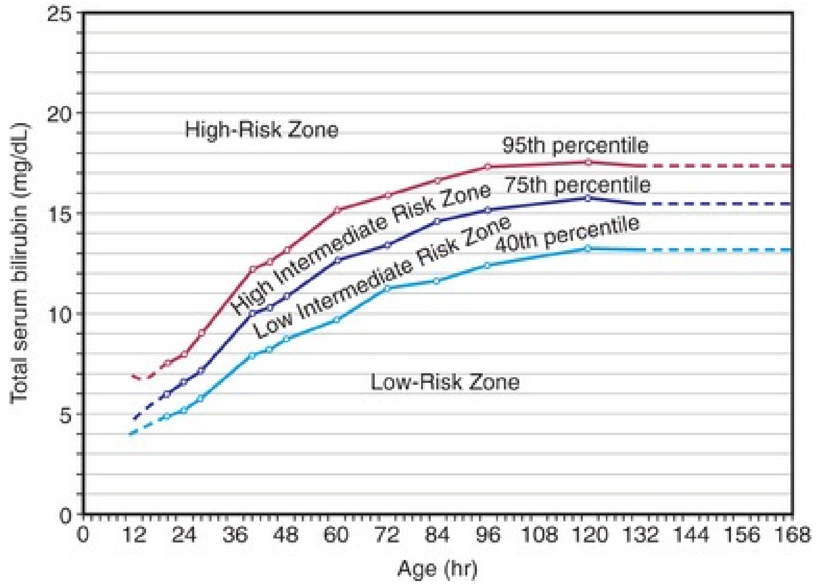


FIG. 123.10 Risk designation of term and near-term well newborns based on their hour-specific serum bilirubin values. The high-risk zone is subdivided by the 95th percentile track. The intermediate -risk zone is subdivided into upper and lower risk zones by the 75th percentile track. The low-risk zone has been electively and statistically defined by the 40th percentile track. (From Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns, *Pediatrics* 103:6–14, 1999.)

The diagnosis of physiologic jaundice in term or preterm infants can be established only by excluding known causes of jaundice on the basis of the history, clinical findings, and laboratory data (see Table 123.4). In general, a search to determine the cause of jaundice should be made if (1) it appears in the 1st 24-36 hr after birth, (2) serum bilirubin is rising at a rate faster than 5 mg/dL/24 hr, (3) serum bilirubin is >12 mg/dL in a full-term infant (especially in the absence of risk factors) or 10-14 mg/dL in a preterm infant, (4) jaundice persists after 10-14 days after birth, or (5) direct bilirubin fraction is >2 mg/dL at any time. Other factors suggesting a pathologic cause of jaundice are family history of hemolytic disease, pallor, hepatomegaly, splenomegaly, failure of phototherapy to lower the bilirubin level, vomiting, lethargy, poor feeding, excessive weight loss, apnea, bradycardia, abnormal vital signs (including hypothermia), light-colored stools, dark urine positive for bilirubin, bleeding disorder, and signs of kernicterus (see Chapter 123.4).

Pathologic Hyperbilirubinemia

Jaundice and its underlying hyperbilirubinemia are considered pathologic if the time of appearance, duration, or pattern varies significantly from that of physiologic jaundice, or if the course is compatible with physiologic jaundice but other reasons exist to suspect that the infant is at special risk for neurotoxicity. It may not be possible to determine the precise cause of an abnormal elevation of unconjugated bilirubin, but many infants with this finding have associated risk factors such as Asian race, prematurity, breastfeeding, and weight loss. Frequently, the terms *exaggerated physiologic jaundice* and *hyperbilirubinemia of the newborn* are used in infants whose primary problem is probably a deficiency or inactivity of bilirubin glucuronyl transferase (**Gilbert syndrome**) rather than an excessive load of bilirubin for excretion (see Table 123.2). The combination of glucose-6-phosphate dehydrogenase (G6PD) deficiency and a mutation of the promoter region of UDP-glucuronyl transferase-1 produces indirect hyperbilirubinemia in the absence of signs of hemolysis. Nonphysiologic hyperbilirubinemia may also be caused by mutations in the gene for bilirubin UDP–glucuronyl transferase.

The greatest risk associated with indirect hyperbilirubinemia is the development of bilirubin-induced neurologic dysfunction, which typically occurs with high indirect bilirubin levels (see Chapter 123.4). The development of kernicterus (bilirubin encephalopathy) depends on the level of indirect bilirubin, duration of exposure to bilirubin elevation, the cause of jaundice, and the infant's well-being. Neurologic injury including kernicterus may occur at lower bilirubin levels in preterm infants and in the presence of asphyxia, intraventricular hemorrhage, hemolysis, or drugs that displace bilirubin from albumin. The exact serum indirect bilirubin level that is harmful for VLBW infants is unclear.

Jaundice Associated With Breastfeeding

Significant elevation in unconjugated bilirubin (**breast milk jaundice**) develops in an estimated 2% of breastfed term infants after the 7th day, with maximal concentrations as high as 10-30 mg/dL reached during the 2nd-3rd wk. If breastfeeding is continued, the bilirubin gradually decreases but may persist for 3-10 wk at lower levels. If nursing is discontinued, the serum bilirubin level falls rapidly, reaching normal range within a few days. With resumption of breastfeeding, bilirubin seldom returns to previously high levels. Phototherapy may be of benefit (see Chapter 123.4). Although uncommon, kernicterus can occur in patients with breast milk jaundice. The etiology of breast milk jaundice is not entirely clear, although β-glucuronidase resulting in deconjugation of bilirubin and increased enterohepatic circulation and other factors in breast milk that might interfere with bilirubin conjugation (e.g., pregnanediol, free fatty acids) have been implicated.

The late jaundice associated with breast milk should be distinguished from an *early onset* , accentuated unconjugated hyperbilirubinemia known as **breastfeeding jaundice** , which occurs in the 1st week after birth in breastfed infants, who normally have higher bilirubin levels than formula-fed infants (Fig. 123.11). Lower milk intake before breast milk production is established can result in dehydration, which hemoconcentrates bilirubin, while also causing fewer bowel movements, which in turn increases the enterohepatic circulation of bilirubin. Prophylactic supplements of glucose water to breastfed infants are associated with higher bilirubin levels, in part because of reduced intake of the higher–caloric density breast milk, and are *not* indicated. Frequent breastfeeding (>10 in 24 hr), rooming-in with night feeding, and ongoing lactation support may reduce the incidence of early breastfeeding jaundice. In addition, supplementation with formula or expressed breast milk is appropriate if the intake seems inadequate, weight loss is excessive, or the infant appears dehydrated.

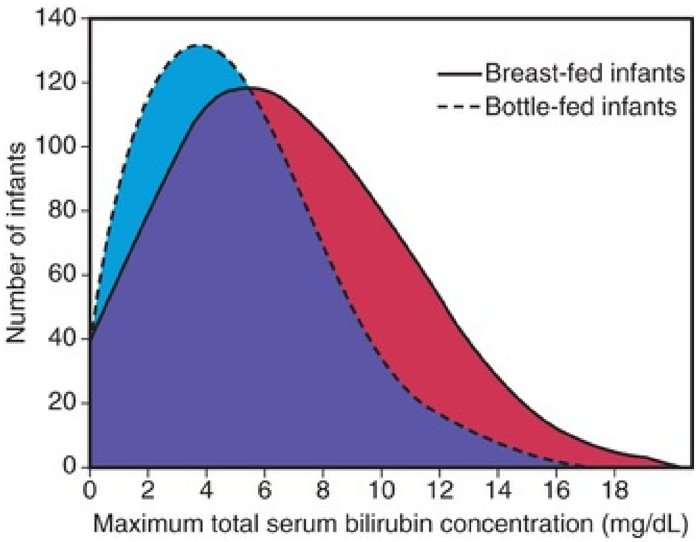

FIG. 123.11 Distribution of maximal bilirubin levels during the 1st wk of life in breastfed and formula-fed white infants weighing >2,500 g. (From Maisels MJ, Gifford K: Normal serum bilirubin levels in the newborn and the effect of breast-feeding, *Pediatrics* 78:837–843, 1986.)

Neonatal Cholestasis

See Chapter 383.1 .

Congenital Atresia of the Bile Ducts

See Chapter 383.1 .

Jaundice persisting for >2 wk or associated with acholic stools and dark urine suggests biliary atresia. All infants with such findings require immediate diagnostic evaluation, including determination of direct bilirubin.

phototherapy

Kernicterus, or **bilirubin encephalopathy** , is a neurologic syndrome resulting from the deposition of unconjugated (indirect) bilirubin in the basal ganglia and brainstem nuclei. The pathogenesis of kernicterus is multifactorial and involves an interaction between unconjugated bilirubin levels, albumin binding and unbound bilirubin levels, passage across the blood-brain barrier (BBB), and neuronal susceptibility to injury. Disruption of the BBB by disease, asphyxia, and other factors and maturational changes in BBB permeability affect risk.

The precise blood level above which indirect-reacting bilirubin or free bilirubin will be toxic for an individual infant is unpredictable. In a large series, however, kernicterus occurred only in infants with a bilirubin >20 mg/dL, 90% of whom were previously healthy, predominantly breastfed, term and near-term infants. The duration of exposure to high bilirubin levels needed to produce toxic effects are unknown; the more immature the infant, the greater the susceptibility to kernicterus. Chapter 123.3 discusses the factors that potentiate the movement of bilirubin across the BBB and into brain cells.

Clinical Manifestations

Signs and symptoms of kernicterus usually appear 2-5 days after birth in term infants and as late as the 7th day in preterm infants, but hyperbilirubinemia may lead to encephalopathy at any time during the neonatal period. The early signs may be subtle and indistinguishable from those of sepsis, asphyxia, hypoglycemia, intracranial hemorrhage, and other acute systemic illnesses in a neonate. Lethargy, poor feeding, and loss of the Moro reflex are common initial signs. Subsequently, the infant may appear gravely ill and prostrate, with diminished tendon reflexes and respiratory distress. Opisthotonos with a bulging fontanel, twitching of the face or limbs, and a shrill, high-pitched cry may follow. In advanced cases, convulsions and spasm occur, with affected infants stiffly extending their arms in an inward rotation with the fists clenched (Table 123.5). Rigidity is rare at this late stage.

Table 123.5

Clinical Features of Kernicterus

ACUTE FORM
Phase 1 (1st 1-2 days): poor suck, stupor, hypotonia, seizures Phase 2 (middle of 1st wk): hypertonia of extensor muscles, opisthotonos, retrocollis, fever Phase 3 (after the 1st wk): hypertonia
CHRONIC FORM
1st yr: hypotonia, active deep tendon reflexes, obligatory tonic neck reflexes, delayed motor skills After 1st yr: movement disorders (choreoathetosis, ballismus, tremor), upward gaze, sensorineural hearing loss

From Dennery PA, Seidman DS, Stevenson DK: Neonatal hyperbilirubinemia, *N Engl J Med* 344:581–590, 2001.

Many infants who progress to these severe neurologic signs die; the survivors are usually seriously damaged but may appear to recover and for 2-3 mo show few abnormalities. Later in the 1st yr, opisthotonos, muscle rigidity, irregular movements, and convulsions tend to recur. In the 2nd yr the opisthotonos and seizures abate, but irregular, involuntary movements, muscle rigidity, or, in some infants, hypotonia increase steadily. By 3 yr of age, the complete neurologic syndrome is often apparent: bilateral choreoathetosis with involuntary muscle spasms, extrapyramidal signs, seizures, mental deficiency, dysarthric speech, high-frequency hearing loss, squinting, and defective upward eye movements. Pyramidal signs, hypotonia, and ataxia occur in a few infants. In mildly affected infants, the syndrome may be characterized only by mild to moderate neuromuscular incoordination, partial deafness, or “minimal brain dysfunction,” occurring singly or in combination; these problems may be unapparent until the child enters school (see Table 123.5).

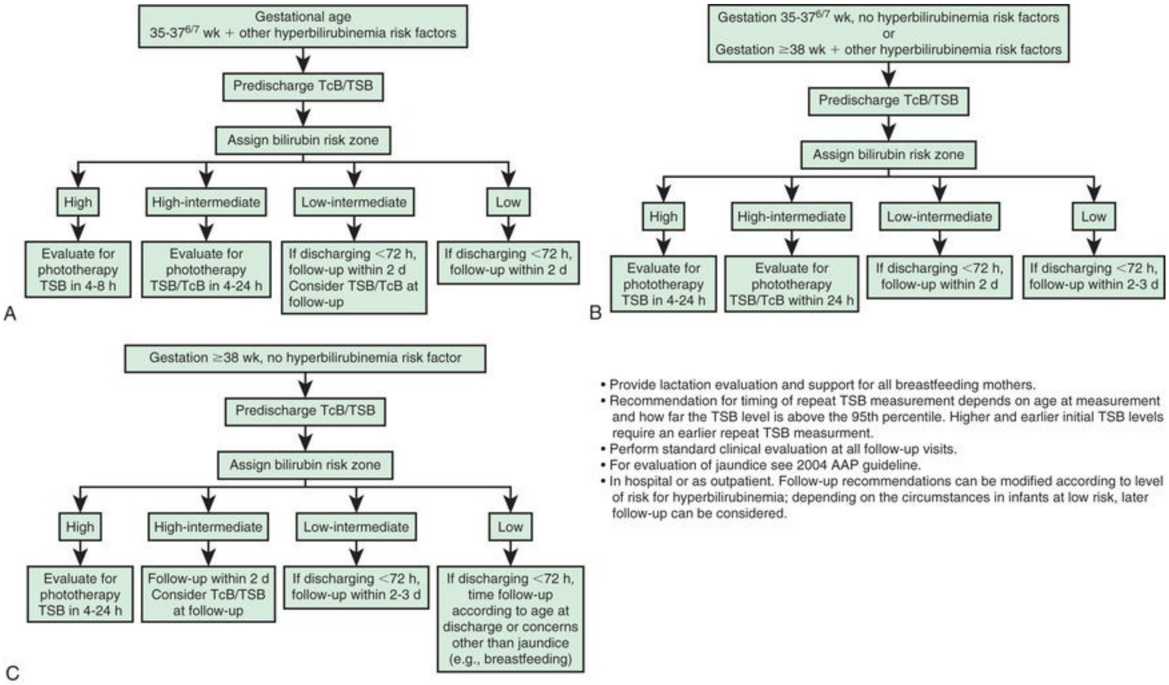
Incidence and Prognosis

By pathologic criteria, kernicterus develops in 30% of infants (all gestational ages) with untreated hemolytic disease and bilirubin levels >25-30 mg/dL. The incidence at autopsy in hyperbilirubinemic preterm infants is 2–16% and is related to the risk factors discussed in Chapter 123.3 . Reliable estimates of the frequency of the clinical syndrome are not available because of the wide spectrum of manifestations. Overt neurologic signs carry a grave prognosis; >75% of infants die, and 80% of affected survivors have bilateral choreoathetosis with involuntary muscle spasms. Developmental delay, deafness, and spastic quadriplegia are common.

Prevention

Although kernicterus has been thought to be a disease of the past, there are reports of neurotoxic effects of bilirubin in term and near-term infants who were discharged as healthy newborns. Effective prevention requires ongoing vigilance and a practical, system-based approach to distinguish infants with benign newborn jaundice from those whose course may be less predictable and potentially harmful. Experts recommend predischarge universal screening for hyperbilirubinemia and assessment of clinical risk factors for severe jaundice and bilirubin-induced neurologic dysfunction. Either total serum bilirubin or transcutaneous bilirubin measurement (interchangeably) is recommended for initial screening, although transcutaneous instruments may be less accurate at higher bilirubin levels (>15 mg/dL) or for infants with darker skin. If transcutaneous levels are documented as ≥15 mg/dL or rising rapidly, confirmation with a total serum bilirubin is recommended. Serum values should also be measured once infants begin phototherapy, because transcutaneous measurement may falsely underestimate total bilirubin in this setting.

Protocols using the hour-specific bilirubin nomogram (see Fig. 123.10), physical examination, and clinical risk factors have been successful in identifying patients at risk for hyperbilirubinemia and candidates for targeted management. Potentially preventable causes of kernicterus include (1) early discharge (<48 hr) with no early follow-up (within 48 hr of discharge); this problem is particularly important in near-term infants (35-37 wk of gestation); (2) failure to check the bilirubin level in an infant noted to be jaundiced in the 1st 24 hr; (3) failure to recognize the presence of risk factors for hyperbilirubinemia; (4) underestimation of the severity of jaundice by clinical (visual) assessment; (5) lack of concern regarding the presence of jaundice; (6) delay in measuring the serum bilirubin level despite marked jaundice or delay in initiating phototherapy in the presence of elevated bilirubin levels; and (7) failure to respond to parental concern regarding jaundice, poor feeding, or lethargy. Fig. 123.12 provides an evidence-based management algorithm for infants. In addition, it is recommended to determine before discharge each infant's risk factors from established protocols (see Table 123.2).



Gestational age
35-37 6/7 wk + other hyperbilirubinemia risk factors
Predischarge TcB/TSB
Assign bilirubin risk zone
High

If discharging <72 h, follow-up within 2-3 d
If discharging <72 h, time follow-up according to age at discharge or concerns other than jaundice (e.g., breastfeeding)
C

- Provide lactation evaluation and support for all breastfeeding mothers.
- Recommendation for timing of repeat TSB measurement depends on age at measurement and how far the TSB level is above the 95th percentile. Higher and earlier initial TSB levels require an earlier repeat TSB measurment.
- Perform standard clinical evaluation at all follow-up visits.
- For evaluation of jaundice see 2004 AAP guideline.
- In hospital or as outpatient. Follow-up recommendations can be modified according to level of risk for hyperbilirubinemia; depending on the circumstances in infants at low risk, later follow-up can be considered.

FIG. 123.12 **Treatment of hyperbilirubinemia. Algorithm providing recommendations for management and follow-up according to predischarge bilirubin measurements, gestation, and risk factors for subsequent hyperbilirubinemia. TcB, Transcutaneous bilirubin; TSB, total serum bilirubin. (Data from Maisels MJ, Bhutani VK, Bogen D, et al: Hyperbilirubinemia in the newborn infant ≥35 weeks' gestation: an update with clarifications, *Pediatrics* 124:1193–1198, 2009.)**

The following approach is further recommended: (1) any infant who is jaundiced before 24 hr requires measurement of total *and* direct serum bilirubin levels and, if it is elevated, evaluation for possible hemolytic disease, and (2) follow-up should be provided within 2-3 days of discharge to all neonates discharged earlier than 48 hr after birth. Early follow-up is particularly important for infants <38 wk of gestation. The timing of follow-up depends on the age at discharge and the presence of risk factors. In some cases, follow-up within 24 hr is necessary. Postdischarge follow-up is essential for early recognition of problems related to hyperbilirubinemia and disease progression. Parental communication with regard to concerns about the infant's skin color and behavioral activities should be addressed early and frequently, including education about potential risks and neurotoxicity. Ongoing lactation promotion, education, support, and follow-up services are essential throughout the neonatal period. Mothers should be advised to nurse their infants every 2-3 hr and to avoid routine supplementation with water or glucose water to ensure adequate hydration and caloric intake.

Treatment of Hyperbilirubinemia

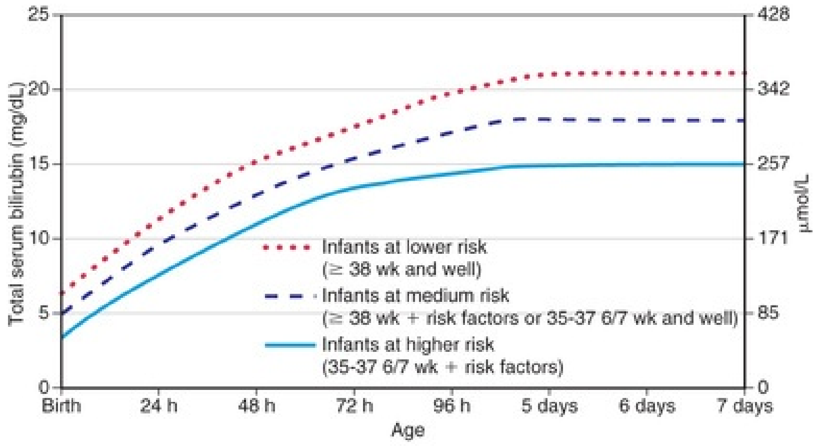
Regardless of the cause, the goal of therapy is to prevent neurotoxicity related to indirect-reacting bilirubin while not causing undue harm. Phototherapy and, if it is unsuccessful, exchange transfusion remain the primary treatment modalities used to keep the maximal total serum bilirubin below pathologic levels (Table 123.6 and Figs. 123.13 and 123.14). The risk of injury to the central nervous system from bilirubin must be balanced against the potential risk of treatment. There is lack of consensus regarding the exact bilirubin level at which to initiate phototherapy. Because phototherapy may require 6-12 hr to have a measurable effect, it must be started at bilirubin levels below those indicated for exchange transfusion. When identified, underlying medical causes of elevated bilirubin and physiologic factors that contribute to neuronal susceptibility should be treated, with antibiotics for septicemia and correction of acidosis (Table 123.7).

Table 123.6

Suggested Maximal Indirect Serum Bilirubin Concentrations (mg/dL) in Preterm Infants

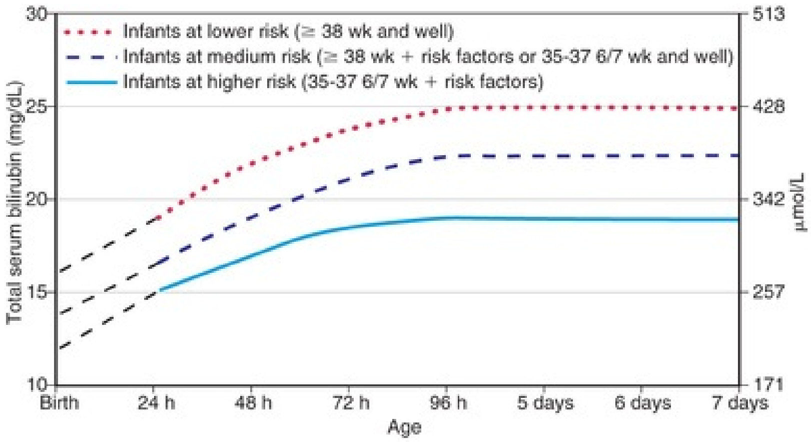
BIRTHWEIGHT (g)	UNCOMPLICATED*	COMPLICATED*
<1,000	12-13	10-12
1,000-1,250	12-14	10-12
1,251-1,499	14-16	12-14
1,500-1,999	16-20	15-17
2,000-2,500	20-22	18-20

[*] Complications include perinatal asphyxia, acidosis, hypoxia, hypothermia, hypoalbuminemia, meningitis, intraventricular hemorrhage, hemolysis, hypoglycemia, or signs of kernicterus. Phototherapy is usually started at 50–70% of the maximal indirect level. If values greatly exceed this level, if phototherapy is unsuccessful in reducing the maximal bilirubin level, or if signs of kernicterus are evident, exchange transfusion is indicated.



- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin < 3.0 g/dL (if measured).
- For well infants 35-37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wks and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2-3 mg/dL (35-50 mmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors.

FIG. 123.13 Guidelines for phototherapy in hospitalized infants of ≥35 wk of gestation. *Note:* These guidelines are based on limited evidence, and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy, which should be used when the total serum bilirubin (TSB) exceeds the line indicated for each category. Infants are designated as "higher risk" because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin. "Intensive phototherapy" implies irradiance in the blue-green spectrum (wavelengths approximately 430-490 nm) of at least 30 μW/cm^2 /nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's skin surface area as possible. Note that irradiance measured below the center of the light source is much greater than that measured at the periphery. Measurements should be made with a radiometer specified by the manufacturer of the phototherapy system. If TSB levels approach or exceed the exchange transfusion line (see Fig. 123.14), the sides of the bassinette, incubator, or warmer should be lined with aluminum foil or white material, to increase both the surface area of the infant exposed and the efficacy of phototherapy. The presence of hemolysis is strongly suggested if the TSB does not decrease or continues to rise in an infant who is receiving intensive phototherapy. Infants who receive phototherapy and have an elevated direct-reacting or conjugated bilirubin value (cholestatic jaundice) may inconsistently have the bronze baby syndrome. G6PD, Glucose-6-phosphate dehydrogenase. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297–316, 2004.)



- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high pitched cry) or if TSB is ≥ 5 mg/dL (85 μmol/L) above these lines.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If infant is well and 35-37 6/7 wk (median risk), can individualize TSB levels for exchange based on actual gestational age.

FIG. 123.14 Guidelines for exchange transfusion in hospitalized infants of ≥35 wk of gestation. *Note:* These suggested levels represent a consensus of most of the committee but are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if the total serum bilirubin (TSB) rises to these levels despite intensive phototherapy. In a readmitted infant, if the TSB level is above the exchange level, TSB measurement should be repeated every 2-3 hr; exchange transfusion should be considered if the TSB remains above the levels indicated after intensive phototherapy for 6 hr. The following B:A (bilirubin:albumin) ratios can be used together with, but not instead of, the TSB level as an additional factor in determining the need for exchange transfusion. G6PD, Glucose-6-phosphate dehydrogenase. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297–316, 2004.)

Table 123.7

Example of a Clinical Pathway for Management of the Newborn Infant Readmitted for Phototherapy or Exchange Transfusion

TREATMENT
Use intensive phototherapy and/or exchange transfusion as indicated in Figs. 123.13 and 123.14 .
LABORATORY TESTS
TSB and direct bilirubin levels Blood type (ABO, Rh) Direct antibody test (Coombs) Serum albumin Complete blood cell count with differential and smear for red cell morphology Reticulocyte count

End-tidal CO concentration (if available)
Glucose-6-phosphate dehydrogenase if suggested by ethnic or geographic origin or if poor response to phototherapy
Urine for reducing substances
If history and/or presentation suggest sepsis, perform blood culture, urine culture, and cerebrospinal fluid for protein, glucose, cell count, and culture.
INTERVENTIONS
If TSB ≥25 mg/dL (428 µmol/L) or ≥20 mg/dL (342 µmol/L) in a sick infant or infant <38 wk gestation, obtain a type and crossmatch, and request blood in case an exchange transfusion is necessary.
In infants with isoimmune hemolytic disease and TSB level rising in spite of intensive phototherapy or within 2-3 mg/dL (34-51 µmol/L) of exchange level (see Fig. 123.14), administer intravenous immune globulin 0.5-1 g/kg over 2 hr and repeat in 12 hr if necessary.
If infant's weight loss from birth is >12% or there is clinical or biochemical evidence of dehydration, recommend formula or expressed breast milk. If oral intake is in question, give intravenous fluids.
FOR INFANTS RECEIVING INTENSIVE PHOTOTHERAPY:
Breastfeed or bottle-feed (formula or expressed breast milk) every 2-3 hr.
If TSB ≥25 mg/dL (428 µmol/L), repeat TSB within 2-3 hr.
If TSB 20-25 mg/dL (342-428 µmol/L), repeat within 3-4 hr. If TSB <20 mg/dL (342 µmol/L), repeat in 4-6 hr. If TSB continues to fall, repeat in 8-12 hr.
If TSB is not decreasing or is moving closer to level for exchange transfusion, or if the TSB/albumin ratio exceeds levels shown in Fig. 123.14 , consider exchange transfusion (see Fig. 123.14 for exchange transfusion recommendations).
When TSB is <13-14 mg/dL (239 µmol/L), discontinue phototherapy.
Depending on the cause of the hyperbilirubinemia, it is an option to measure TSB 24 hr after discharge to check for rebound.

TSB, Total serum bilirubin.

From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297–316, 2004.

Phototherapy

Clinical jaundice and indirect hyperbilirubinemia are reduced by exposure to high-intensity light in the visible spectrum. Bilirubin absorbs light maximally in the blue range (420-470 nm). Broad-spectrum white, blue, and special narrow-spectrum (super) blue lights have been effective in reducing bilirubin levels. Bilirubin in the skin absorbs light energy, causing several photochemical reactions. One major product from phototherapy is a result of a reversible photoisomerization reaction converting the toxic native unconjugated 4Z,15Z-bilirubin into an unconjugated configurational isomer, 4Z,15E-bilirubin, which can then be excreted in bile without conjugation. The other major product from phototherapy is lumirubin, which is an irreversible structural isomer converted from native bilirubin that can be excreted by the kidneys in the unconjugated state.

The therapeutic effect of phototherapy depends on the light energy emitted in the effective range of wavelengths, the distance between the lights and the infant, and the surface area of exposed skin, as well as the rate of hemolysis and in vivo metabolism and excretion of bilirubin. Available commercial phototherapy units vary considerably in spectral output and the intensity of radiance emitted; therefore the wattage can be accurately measured only at the patient's skin surface. Dark skin does not reduce the efficacy of phototherapy. Maximal intensive phototherapy should be used when indirect bilirubin levels approach those noted in Fig. 123.13 and Table 123.7 . Such therapy includes using “special blue” fluorescent tubes, placing the lamps within 15-20 cm (6-8 inches) of the infant, and putting a fiberoptic phototherapy blanket under the infant's back to increase the exposed surface area.

The use of phototherapy has decreased the need for exchange transfusion in term and preterm infants with hemolytic and nonhemolytic jaundice. When indications for exchange transfusion are present, phototherapy should not be used as a substitute; however, phototherapy may reduce the need for repeated exchange transfusions in infants with hemolysis. Conventional phototherapy is applied continuously, and the infant is turned frequently for maximal skin surface area exposure. It should be discontinued as soon as the indirect bilirubin concentration has reduced to levels considered safe with respect to the infant's age and condition. Serum bilirubin levels and hematocrit should be monitored every 4-8 hr in infants with hemolytic disease and those with bilirubin levels near toxic range for the individual infant. Others, particularly older neonates, may be monitored less frequently. Serum bilirubin monitoring should continue for at least 24 hr after cessation of phototherapy in patients with hemolytic disease, because unexpected rises in bilirubin may occur, requiring further treatment. Skin color cannot be relied on for evaluating the effectiveness of phototherapy; the skin of babies exposed to light may appear to be almost without jaundice in the presence of marked hyperbilirubinemia. Although not necessary for all affected infants, intravenous fluid supplementation added to oral feedings may be beneficial in dehydrated patients or infants with bilirubin levels nearing those requiring exchange transfusion.

Complications associated with phototherapy include loose stools, erythematous macular rash, purpuric rash associated with transient porphyrinemia, overheating, dehydration (increased insensible water loss, diarrhea), hypothermia from exposure, and a benign condition called “bronze baby syndrome,” which occurs in the presence of direct hyperbilirubinemia. Phototherapy is contraindicated in the presence of porphyria. Before phototherapy is initiated, the infant's eyes should be closed and adequately covered to prevent light exposure and corneal damage. Body temperature should be monitored, and the infant should be shielded from bulb breakage. Irradiance should be measured directly. In infants with hemolytic disease, care must be taken to monitor for the development of anemia, which may require transfusion. *Anemia may develop despite lowering of bilirubin levels.* Clinical experience suggests that long-term adverse biologic effects of phototherapy are absent, minimal, or unrecognized.

The term **bronze baby syndrome** refers to a dark, grayish brown skin discoloration sometimes noted in infants undergoing phototherapy. Almost all infants observed with this syndrome have had significant elevation of direct-reacting bilirubin and other evidence of obstructive liver disease. The discoloration may result from photo-induced modification of porphyrins, which are often present during cholestatic jaundice and may last for many months. Despite the bronze baby syndrome, phototherapy can continue if needed.

Intravenous Immune Globulin

The administration of intravenous immunoglobulin (IVIG) is an adjunctive treatment for hyperbilirubinemia caused by *isoimmune hemolytic disease* . Its use is recommended when serum bilirubin is approaching exchange levels despite maximal interventions, including phototherapy. IVIG (0.5-1.0 g/kg/dose; repeat in 12 hr) reduces the need for exchange transfusion in both ABO and Rh hemolytic disease, presumably by reducing hemolysis.

Metalloporphyrins

A possible adjunct therapy is the use of metalloporphyrins for hyperbilirubinemia. The metalloporphyrin Sn-mesoporphyrin (SnMP) offers promise as a drug candidate. The proposed mechanism of action is competitive enzymatic inhibition of the rate-limiting conversion of heme-protein to biliverdin (an intermediate metabolite in the production of unconjugated bilirubin) by heme-oxygenase. A single intramuscular dose on the 1st day of life may reduce the need for subsequent phototherapy. Such therapy may be beneficial when jaundice is anticipated, particularly in patients with ABO incompatibility or G6PD deficiency, or when blood products are objected to, as with Jehovah's Witness patients. Complications from metalloporphyrins include transient erythema if the infant is receiving phototherapy. Administration of SnMP may reduce bilirubin levels and decrease both the need for phototherapy and the duration of hospital stay; however, it remains unclear whether treatment with metalloporphyrins for unconjugated hyperbilirubinemia will alter the risk of kernicterus or long-term neurodevelopment impairment. Data on efficacy, toxicity, and long-term benefit are still being evaluated.

Exchange Transfusion

Double-volume exchange transfusion is performed if intensive phototherapy has failed to reduce bilirubin levels to a safe range and the risk of kernicterus exceeds the procedural risk. Potential complications from exchange transfusion are not trivial and include metabolic acidosis, electrolyte abnormalities, hypoglycemia, hypocalcemia, thrombocytopenia, volume overload, arrhythmias, NEC, infection, graft-versus-host disease, and death. This widely accepted treatment is repeated if necessary to keep indirect bilirubin levels in a safe range (see Fig. 123.14 and Table 123.7).

Various factors may influence the decision to perform a double-volume exchange transfusion in an individual patient. The appearance of clinical signs suggesting kernicterus is an indication for exchange transfusion at any level of serum bilirubin. A healthy full-term infant with physiologic or breast milk jaundice may tolerate a concentration slightly higher than 25 mg/dL with no apparent ill effect, whereas kernicterus may develop in a sick premature infant at a significantly lower level. A level approaching that considered critical for the individual infant may be an indication for exchange transfusion during the 1st or 2nd day after birth, when a further rise is anticipated, but not typically after the 4th day in a term infant or after the 7th day in a preterm infant, because an imminent fall may be anticipated as the hepatic conjugating mechanism becomes more effective.

CHAPTER 124

Blood Disorders

124.1

Anemia in the Newborn Infant

Patrick T. McGann, Russell E. Ware

Keywords

ABO incompatibility
anemia of prematurity
fetomaternal hemorrhage
G6PD deficiency
hereditary spherocytosis
physiologic nadir

Anemia is a common laboratory and clinical finding in the newborn period and carries a broad differential diagnosis. Anemia in the newborn may be acute or chronic, and its clinical manifestations range from an asymptomatic laboratory finding to life-threatening signs and symptoms. The diagnosis and interpretation of anemia in the newborn infant are therefore complex and require careful consideration of the gestational age and general health of the infant, details of the perinatal course and delivery, and information regarding the general health of the mother both during pregnancy and through delivery into the postpartum period.

Before interpreting hemoglobin and hematocrit values for infants, it is important to understand the pathophysiology of hemoglobin-oxygen binding and delivery, both before and after birth. Because of the hypoxic environment in utero and the lack of direct gas exchange with the ambient atmosphere, fetal hemoglobin (HbF) predominates throughout late gestation because of its increased affinity to bind and transport oxygen compared to the mother's adult hemoglobin. Despite the predominance of HbF, the in utero environment remains hypoxic, such that the normal hemoglobin concentration is relatively high at birth.

Normal Hematocrit and Hemoglobin Concentrations in Newborn Infants

The diagnostic approach to anemia in the newborn infant begins comparing laboratory results with reference ranges for both gestational age and postnatal age. Although significant variability exists in suggested reference ranges, data collected from more than 25,000 preterm and term infants through the 1st 28 days of life have provided robust data-driven reference ranges. These data, illustrated in Fig. 124.1 , demonstrate a near-linear increase in hemoglobin and hematocrit between 22 and 40 wk of gestation. Notably, the mean corpuscular volume (MCV) in neonates is strikingly higher than toddlers and older children, with normal values ranging from about 100-115 fL at birth. An MCV <100 fL at birth should prompt consideration of underlying α-thalassemia trait or maternal iron deficiency.

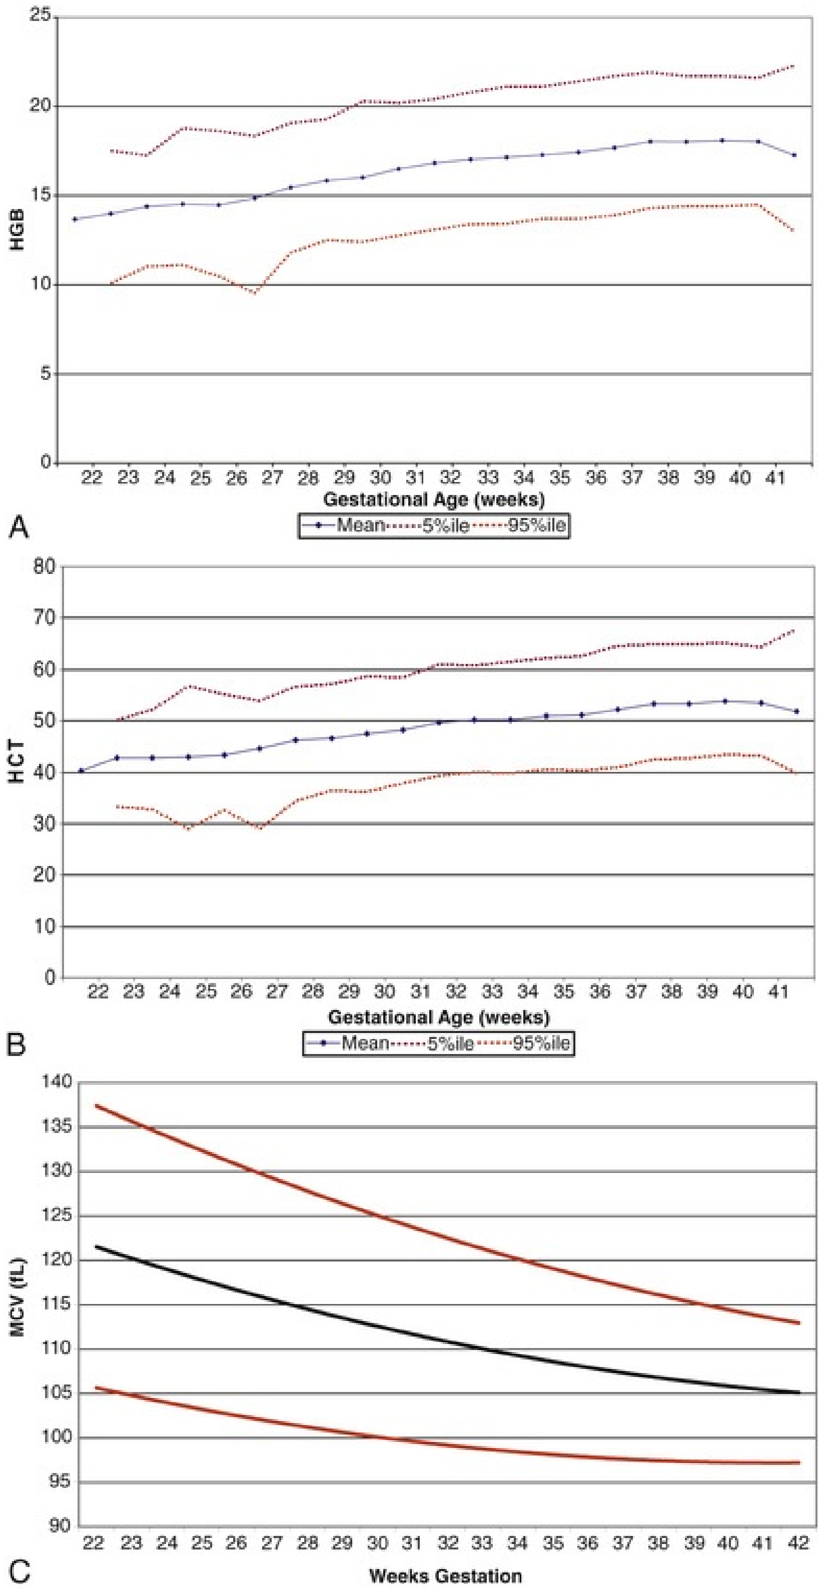

FIG. 124.1 Reference range for hematocrit and hemoglobin concentration according to gestational age. A and B, Reference ranges (5th percentile, mean, and 95th percentile) are shown for blood hemoglobin (A) and hematocrit (B). Concentrations were obtained during the 1st 6 hr after birth, among patients 22-42 wk gestation. Values were

excluded if the diagnosis included abruption, placenta previa, or known fetal anemia, or if a blood transfusion was given before the first hemoglobin was measured. C, References ranges for mean corpuscular volume (MCV) in neonates on 1st day after birth. The *lower line* shows the 5th percentile values, the *middle line* shows the mean values, and the *upper line* shows the 95th percentile values. (From Christensen RD, Jopling HE, Jopling J, Wiedemeir SE: The CBC: reference ranges for neonates, *Semin Perinatol* 33(1):3–11, 2009.)

Over the first days and weeks of postnatal life, increased oxygen in the environment reduces the erythropoietic drive, and this normal developmental and physiologic process results in a slow decrease in hematocrit and hemoglobin concentration. Fig. 124.2 demonstrates the expected decrease in hematocrit and hemoglobin concentration according to postnatal age for both term/postterm (Fig. 124.2*A* and *B*) and preterm (29-34 wk gestation) infants. The *lower dashed lines* in Fig. 124.2 represent the 5th percentile, below which a diagnosis of neonatal anemia should be defined. Eventually, oxygen delivery becomes limiting enough to stimulate new active erythropoiesis, and the hemoglobin concentration begins to rise. This **physiologic nadir** usually occurs between 6 and 10 wk of life for term infants, with a typical low hemoglobin value of 9-11 g/dL, while preterm infants reach their nadir earlier, at 4-8 wk of age with a hemoglobin concentration of 7-9 g/dL.

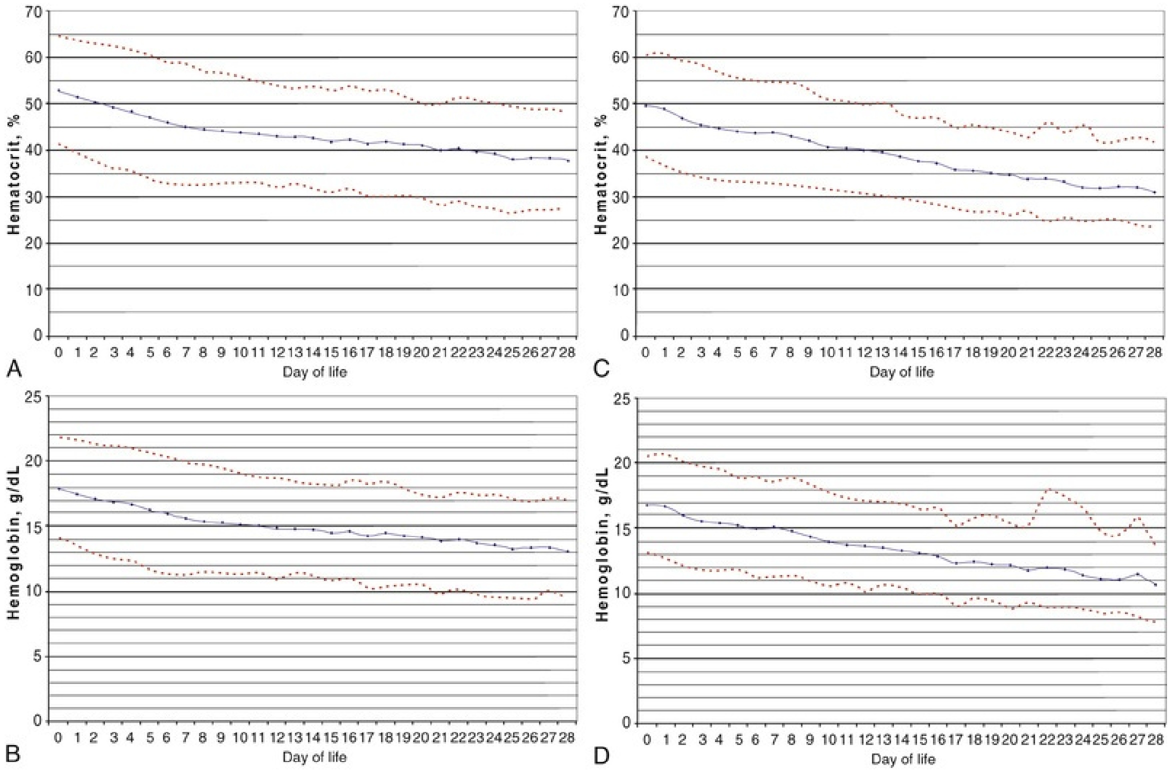

FIG. 124.2 **Reference range for hematocrit and hemoglobin concentration during 1st 28 days of life. A and B, Late preterm and term infants (35-42 wk gestation). C and D, Preterm infants (29-34 wk gestation). The reference ranges are shown for hematocrit (A and C) (41,957 patients) and blood hemoglobin (B and D) (39,559 patients) during the 28 days after birth. Values were divided into 2 groups (A/B and C/D) on the basis of gestational age at delivery. Patients were excluded when their diagnosis included abruption, placenta previa, or fetal anemia, or when a blood transfusion was given. Analysis was not possible for patients <29 wk gestation because virtually all these had repeated phlebotomy and erythrocyte transfusions. (From Jopling J, Henry E, Wiedmeier SE, Christensin RD: Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period: data from a multihospital health care system, *Pediatrics* 123(2):e333–e337, 2009.)**

Classification of Anemia and Diagnostic Evaluation

As with any diagnostic approach to anemia, low hemoglobin concentration in the newborn period can be classified into 3 broad categories: blood loss; erythrocyte destruction; or underproduction of erythrocytes. Table 124.1 summarizes the most common causes of neonatal anemia according to these categories.

Table 124.1

Differential Diagnosis of Neonatal Anemia

BLOOD LOSS	**↑ RBC DESTRUCTION**	**↓ RBC PRODUCTION**
Iatrogenic blood loss (phlebotomy)	***Immune-Mediated Hemolysis***	Physiologic anemia and anemia of prematurity
Placental hemorrhage	Rh incompatibility	Infection (rubella, CMV, parvovirus B19)
Placental previa	ABO incompatibility	Bone marrow suppression (acute stress in perinatal period)
Injury of umbilical or placental vessels	Minor antigen incompatibility	Hemoglobinopathy (γ-globin mutation, unstable β-hemoglobinopathy, α-thalassemia major)
Fetomaternal transfusion	***RBC Membrane Disorders***	Bone marrow suppression (CMV, EBV)
Fetoplacental transfusion	Hereditary spherocytosis	Diamond Blackfan anemia
Twin-twin transfusion	Hereditary elliptocytosis	Schwachman-Diamond syndrome
Acute perinatal hemorrhage (e.g., cesarean birth, other obstetric trauma)	Hereditary pyropoikilocytosis	Congenital dyserythropoietic anemia
Chronic in utero blood loss	Hereditary stomatocytosis	Fanconi anemia
	RBC Enzyme Disorders	Pearson syndrome
	G6PD deficiency	Congenital leukemia
	Pyruvate kinase	

	deficiency	

CMV, Cytomegalovirus, EBV, Epstein-Barr virus; G6PD, glucose-6-phosphate dehydrogenase; RBC, red blood cell.

Prior to laboratory testing, a complete medical history, including careful review of the pregnancy and perinatal course, and a careful physical examination are important because they often suggest a specific diagnosis more effectively than extensive laboratory testing. A simple and efficient laboratory workup is critical to the timely diagnosis and associated treatment of neonatal anemia. In addition to a complete blood count (CBC), additional laboratory tests on the infant include the reticulocyte count, direct antiglobulin test, serum bilirubin, infant and maternal blood ABO group, and Rh type. The mother should also be screened with an indirect (serum) antiglobulin test for erythrocyte alloantibodies, and the Kleihauer-Betke test can identify fetal erythrocytes in the maternal circulation (Fig. 124.3). Fig. 124.4 shows a proposed diagnostic approach to anemia in newborn infants. Hemolytic anemia is usually associated with difficult-to-treat **hyperbilirubinemia** (Fig. 124.5), whereas **congenital aregenerative anemias** (e.g., Diamond-Blackfan anemia) usually do not manifest jaundice but have other features (Table 124.2).

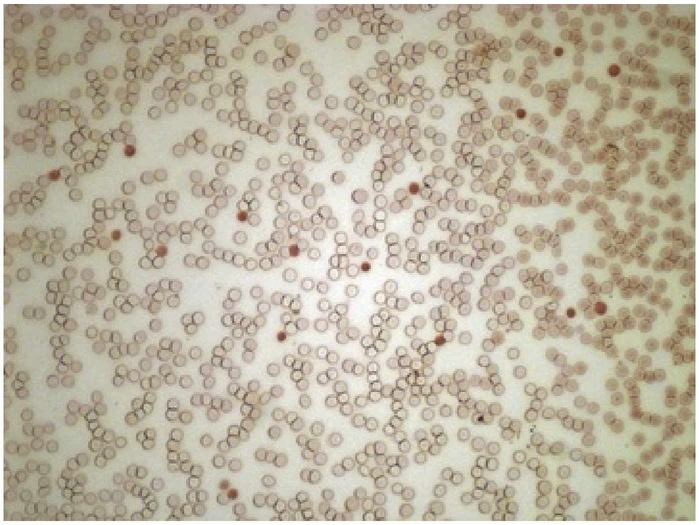

FIG. 124.3 **Acid elution technique of Kleithauer (Kleihauer-Betke test). Fetal red blood cells stain with eosin and appear *dark* . Adult RBCs do not stain and appear as “ghosts.” (From Liley HG, Gardener G, Lopriore E, Smits-Wintjens V: Immune hemolytic disease. In Orkin SH, Nathan DG, Ginsburg D, et al, editors: *Nathan and Oski's hematology and oncology of infancy and childhood,* ed 8, Philadelphia, 2015, Elsevier, Fig 3-2.)**

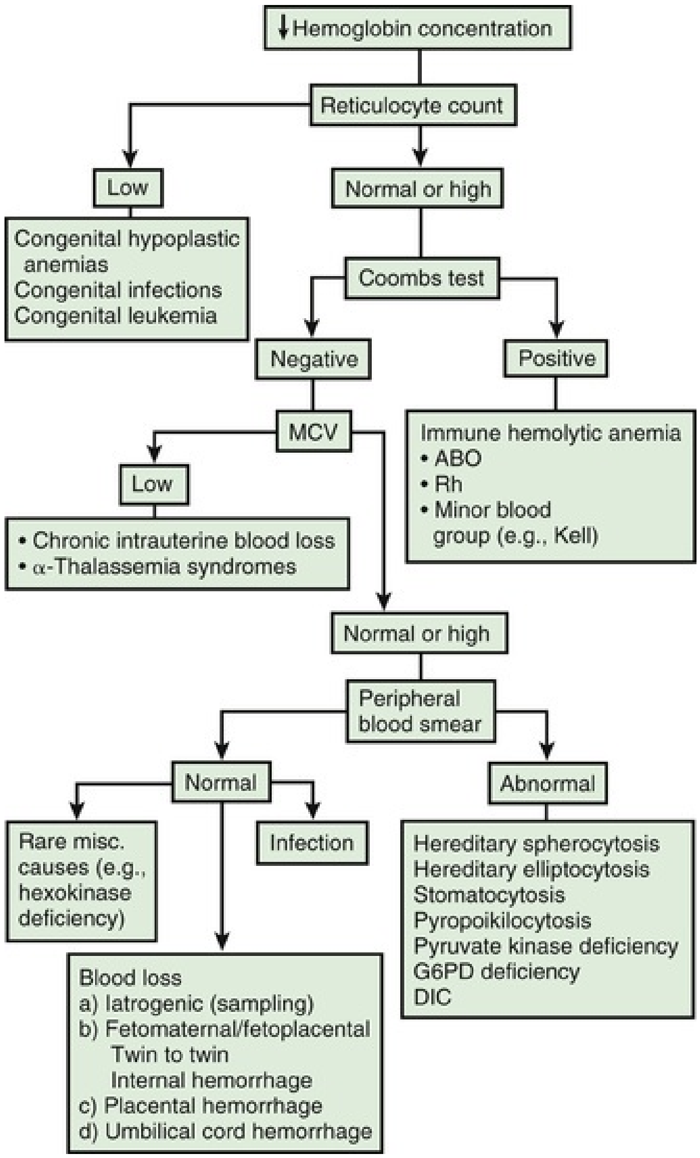

↓Hemoglobin concentration

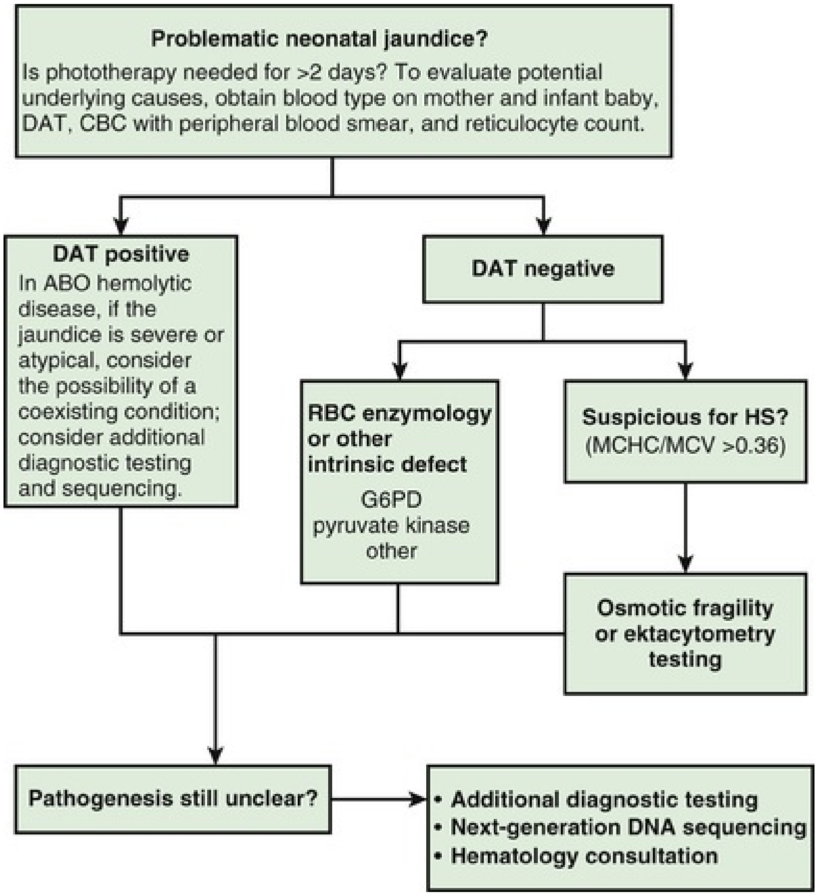
(Modified from Blanchette VS, Zipursky A: Assessment of anemia in newborn infants, *Clin Perinatol* 11:489–510, 1984.)**



Problematic neonatal jaundice?
Is phototherapy needed for >2 days? To evaluate potential underlying causes, obtain blood type on mother and infant baby, DAT, CBC with peripheral blood smear, and reticulocyte count.
DAT positive
In ABO hemolytic disease, if the jaundice is severe or atypical, consider the possibility of a coexisting condition; consider additional diagnostic testing and sequencing.
DAT negative
RBC enzymology or other intrinsic defect
G6PD
pyruvate kinase
other
Suspicious for HS? (MCHC/MCV >0.36)
Osmotic fragility or ektacytometry testing
Pathogenesis still unclear?
• Additional diagnostic testing
• Next-generation DNA sequencing
• Hematology consultation

FIG. 124.5 Evaluation of neonate with problematic jaundice of unclear cause. Not all neonates who receive phototherapy for 2 days or more have hemolytic jaundice. However, if hemolytic jaundice is suspected, this algorithm for stepwise evaluation of the cause might be useful. CBC, Complete blood count; DAT, direct antiglobulin test; EMA, eosin 5-maleimide; G6PD, glucose 6-phosphate dehydrogenase; HS, hereditary spherocytosis; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell. (From Christensen RD: Neonatal erythrocyte disorders. In Gleason CA, Juul SE, editors: *Avery's diseases of the newborn,* ed 10, Philadelphia, 2018, Elsevier, Fig 81-15.)

Table 124.2

Syndromes Associated With Congenital Hyporegenerative Anemia

SYNDROME	PHENOTYPIC FEATURES	GENOTYPIC FEATURES
Adenosine deaminase deficiency	Autoimmune hemolytic anemia, reduced erythrocyte adenosine deaminase activity	AR, 20q13.11
Congenital dyserythropoietic anemias	Type I (rare): megaloblastoid erythroid hyperplasia and nuclear chromatin bridges between nuclei Type II (most common): hereditary erythroblastic multinuclearity with positive acidified serum test result,	Type I: 15q15.1-q15.3 Type II: 20q11.2 Type III: 15q21

	increased lysis to anti-i antibodies Type III: erythroblastic multinuclearity (“gigantoblasts”), macrocytosis	
Diamond-Blackfan syndrome	Steroid-responsive hypoplastic anemia, often macrocytic after 5 mo of age	AR; sporadic mutations and AD inheritance described; 19q13.2, 8p23.3-p22
Dyskeratosis congenita	Hypoproliferative anemia usually presenting between 5 and 15 yr of age	X-linked recessive, locus on Xq28; some cases with AD inheritance
Fanconi syndrome	Steroid-responsive hypoplastic anemia, reticulocytopenia, some macrocytic RBCs, shortened RBC life span Cells are hypersensitive to DNA cross-linking agents.	AR, multiple genes: complementation; group A 16q24.3; group B Xp22.3; group C 9q22.3; group D2 3p25.3; group E 6p22-p21; group F 11p15; group G 9p13
Osler hemorrhagic telangiectasia syndrome	Hemorrhagic anemia	AD, 9q34.1
Osteopetrosis	Hypoplastic anemia from marrow compression; extramedullary erythropoiesis	AR, 16p13, 11q13.4-q13.5; AD, 1p21; lethal, reduced levels of osteoclasts
Pearson syndrome	Hypoplastic sideroblastic anemia, marrow cell vacuolization	Pleioplasmatic rearrangement of mitochondrial DNA; X-linked or AR
Peutz-Jeghers syndrome	Iron-deficiency anemia from chronic blood loss	AD, 19p13.3
ATR-X and ATR-16 syndromes	ATR-X: hypochromic, microcytic anemia; mild form of hemoglobin H disease ATR-16: more significant hemoglobin H disease and anemia are present.	ATR-16, 16p13.3, deletions of α-globin locus

AD, Autosomal dominant; AR, autosomal recessive; ATR-16, chromosome 16–related α-thalassemia/mental retardation; ATR-X, X-linked α-thalassemia/mental retardation; RBC, red blood cell.

From Christensen RD: Neonatal erythrocyte disorders. In Gleason CA, Juul SE, editors: *Avery's diseases of the newborn,* ed 10, Philadelphia, 2018, Elsevier (Table 81-2).

Review of the peripheral blood smear is an essential component of the evaluation of neonatal anemia. The presence of reticulocytes and nucleated red blood cells (RBCs) indicate chronic anemia with compensatory active erythropoiesis, while distinct erythrocyte morphologies (e.g., elliptocytes, acanthocytes) suggest a congenital intrinsic hemolytic anemia. The presence of spherocytes (often **microspherocytes**) is consistent with immune-mediated hemolysis but can also indicate **hereditary spherocytosis** ; the direct antiglobulin test (DAT, formerly the direct Coombs test) is needed to distinguish these 2 important diagnoses (Fig. 124.6). Neonatal blood smears often include atypical erythrocyte morphology with macrocytosis, poikilocytosis, and anisocytosis that reflect normal fetal erythropoiesis, and an experienced hematologist or pathologist may be required to identify a pathologic feature (Table 124.3) (see Chapter 474).

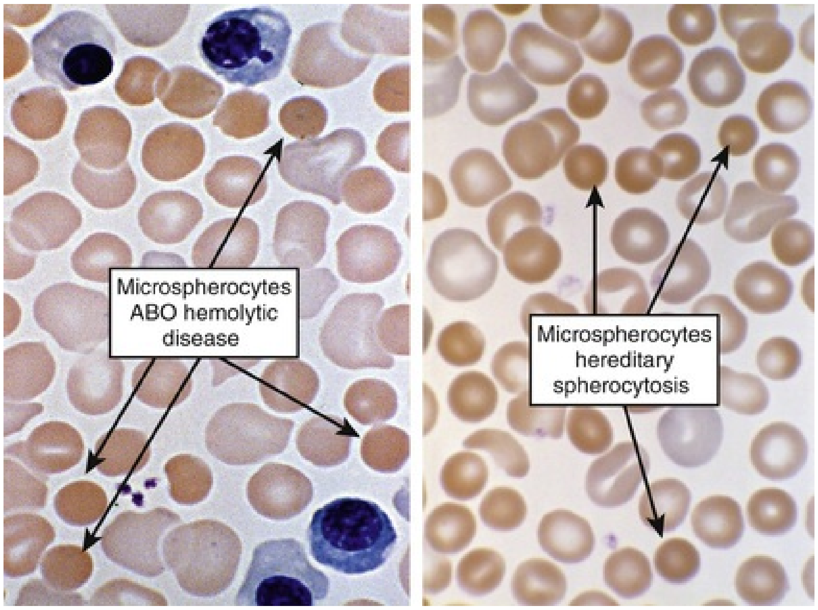


FIG. 124.6 Microspherocytes. *Left,* Neonate with ABO hemolytic disease. *Right,* Neonate with hereditary spherocytosis (*right*). (From Christensen RD: Neonatal erythrocyte disorders. In Gleason CA, Juul SE, editors: *Avery's diseases of the newborn,* ed 10, Philadelphia, 2018, Elsevier, Fig 81-8.)

Table 124.3

Morphologic Abnormalities of Erythrocytes From Neonates With Jaundice

ABNORMAL ERYTHROCYTE MORPHOLOGY	MOST LIKELY CAUSES	SUGGESTED LABORATORY TESTING/FINDINGS	OTHER FEATURES
Microspherocytes	Hereditary spherocytosis	DAT (−) EMA flow (+) Persistent spherocytosis Reticulocytosis	MCHC/MCV elevated (>36, likely >40)
	ABO hemolytic disease	DAT (+) Transient spherocytosis Reticulocytosis	MCHC/MCV normal (<36, likely <34)
Elliptocytes	Hereditary elliptocytosis	DAT (−)	MCHC normal MCV normal
Bite and blister cells	G6PD deficiency	G6PD enzyme activity	Typically affects males, but rarely females are also affected Ethnicity of equatorial origin
	Unstable hemoglobin	Heinz body preparation	
Echinocytes	PK deficiency	PK enzyme activity	Autosomal recessive, likely to have no family history
	Other	Quantify activity of	

	glycolytic enzyme deficiency	other glycolytic enzymes	
Schistocytes	DIC and/or perinatal asphyxia Heinz body HA	Low levels of FV and FVIII, elevated levels of D-dimers Positive result of Heinz body preparation	Low or falling platelet count Normal to high IPF Normal to high MPV DIC, perinatal asphyxia ADAMTS-13 deficiency, early neonatal HUS, and giant hemangiomas all involve platelet consumption from endothelial injury and all have a similar neonatal presentation
	ADAMTS-13 deficiency (TTP)	Severely decreased ADAMTS-13 activity (<0.1 U/mL) high levels of LDH	
	Neonatal hemolytic-uremic syndrome	Acute renal failure	
	Homozygous protein C deficiency	Severely decreased functional protein C activity (<1%)	
	Giant hemangioma	May be internal or external	

DAT, Direct antiglobulin test; DIC, disseminated intravascular coagulation; EMA, eosin 5-maleimide; FV, factor V; FVIII, factor VIII; G6PD, glucose-6-phosphate dehydrogenase; HA, hemolytic anemia; HUS, hemolytic uremic syndrome; IPF, immature platelet fraction; LDH, lactic dehydrogenase; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; MPV, mean platelet volume; PK, pyruvate kinase; TTP, thrombotic thrombocytopenic purpura.

From Christensen RD, Yaish HM: Hemolytic disorders causing severe neonatal hyperbilirubinemia, *Clin Perinatol* 42:515–527, 2015 (Table 3).

Red Blood Cell Loss

Blood loss is the most common cause of neonatal anemia. Repeated or frequent phlebotomy for routine laboratory tests, especially from premature or acutely ill neonates, is one of the most common causes of anemia. Several reports have documented large volumes of blood removed for laboratory testing among children in neonatal intensive care units (NICUs), with weekly phlebotomy volumes ranging from 15–30% of the infant's total blood volume (11-22 mL/kg/wk). Most other causes of blood loss occur just before or during delivery, such as placental abruption, and fetal hemorrhage is more common in emergent or traumatic deliveries (see Table 124.1).

Fetomaternal hemorrhage (FMH) is caused by bleeding from the fetal into the maternal circulation, either before or during delivery. Such bleeding occurs to some extent in most pregnancies, although the volume lost is typically small.

Estimates suggest that more substantial FMH, defined as >30 mL of fetal blood, occurs in 3 per 1,000 births, with *large* (>80 mL) or *massive* (>150 mL) FMH occurring in 0.9 and 0.2 per 1,000 births, respectively. Blood loss during gestation can be slow and well compensated by the fetus in terms of both blood volume and oxygen delivery, but faster or larger bleeds will not be fully compensated. Therefore the presentation of FMH is variable, but *decreased or absent fetal movement* is the most common antenatal presentation and should be associated with a high degree of clinical suspicion. After delivery, infant pallor, hypotension, and poor perfusion will indicate severe anemia. To diagnose FMH, the classic *Kleihauer-Betke test*, which identifies fetal erythrocytes containing HbF resistant to acid elution, is technically the gold standard but is labor intensive, highly dependent on the skills of the technician, and often not available as a rapid or point-of-care test (see Fig. 124.3). Some advanced laboratories offer a more precise test using flow cytometry to quantify fetal cells in the maternal circulation.

Red Blood Cell Destruction

RBC destruction is an important cause of neonatal anemia and most frequently reflects elimination of erythrocytes by immune-mediated mechanisms, which result from RBC antigen incompatibilities between the infant and mother. **Hemolytic disease of the fetus and newborn (HDFN)** is a broad term used to describe any fetus or infant who develops alloimmune hemolysis caused by the presence of maternal antibodies against RBC antigens within the circulation of the child (see Chapter 124.2). HDFN caused by anti-RhD antibodies, occurring in RhD-positive infants born to RhD-negative mothers, is the most severe form because of the highly immunogenic nature of the RhD antigen. ABO incompatibility, most often a mismatch between group O mothers and their non–group O infants, affects approximately 15% of pregnancies but is usually less severe than Rh disease, with only 4% of incompatible pregnancies resulting in neonatal hemolytic disease. Unlike Rh disease, in which sensitization usually occurs in the first pregnancy and HDFN occurs in subsequent pregnancies, ABO incompatibility can occur during a woman's first pregnancy, since group O mothers have naturally occurring anti-A and anti-B antibodies. A positive DAT on the infant's blood and a positive indirect antiglobulin test (IAT; also known as the antibody screen) in the mother provide diagnostic evidence of HDFN.

In addition to immune-mediated mechanisms of erythrocyte destruction,

congenital RBC enzyme and membrane disorders also can result in hemolytic anemia and jaundice within the neonatal period. The erythrocyte membrane is a complex structure with numerous critical proteins and lipids that result in a durable, flexible, circulating biconcave disc shape. Genetic deficiencies or abnormalities in RBC membrane proteins (e.g., ankyrin, band 3, α-spectrin, β-spectrin, protein 4.2) result in instability of the RBC membrane, decreased cellular deformability, and shape changes; the abnormal erythrocytes undergo splenic entrapment and removal by macrophages. **Hereditary spherocytosis (HS)** , an autosomal dominant condition characterized by spherical erythrocytes, is the most common RBC membrane disorder, affecting 1 in 2,500-5,000 individuals of European descent. Nearly half of infants born with HS will develop jaundice early in the newborn period.

Hereditary elliptocytosis (HE) , another autosomal dominant inherited erythrocyte membranopathy, characterized by elliptical-shaped erythrocytes, is a less common and less severe RBC membrane disorder. In contrast, **hereditary pyropoikilocytosis (HPP)** is an autosomal recessive RBC membrane disorder resulting in striking morphologic shape changes (poikilocytosis) noted on the peripheral blood smear, some of which resemble thermally damaged erythrocytes. HPP is most common in infants of African descent and can be associated with severe anemia and hemolysis in the newborn period. There is substantial clinical and genetic overlap between HPP and HE, because infants with HPP often have a family history of HE and may develop a milder condition resembling HE later in childhood. Clinical suspicion for a RBC membranopathy begins with a positive family history of hemolytic anemia, especially in an infant who develops early jaundice in the 1st 24 hr of life. The diagnostic evaluation should include a negative DAT, indirect hyperbilirubinemia, and hallmark features noted on the peripheral blood smear. The degree of anemia is variable, and reticulocytosis may also be present.

Erythrocyte enzymopathies are another important, but less common, etiology of neonatal anemia. Circulating RBCs lack a nucleus, mitochondria, or other essential organelles and thus rely solely on critical metabolic pathways to allow for their function in the transport and delivery of oxygen. Several enzymes are especially important to RBC metabolism and may result in hemolytic anemia when deficient. **Glucose-6-phosphate dehydrogenase (G6PD) deficiency** is the most common of these RBC enzymopathies. G6PD deficiency is a common X-linked disorder affecting >400 million people worldwide. There are several classes of G6PD deficiency with varying degrees of clinical severity, but most affected persons are asymptomatic. In the setting of oxidative stress (drugs, infection, certain foods), however, some persons with G6PD deficiency may develop acute hemolytic anemia. There is a several-fold increase in the incidence of neonatal jaundice in G6PD-deficient infants, with jaundice typically occurring on day 2-3 of life. Severe anemia with reticulocytosis is not common, but hyperbilirubinemia in the setting of G6PD deficiency can be severe and prolonged. Clinical testing measuring G6PD activity can be performed (<1–2% suggests G6PD deficiency), but the testing will not be accurate in the setting of acute hemolysis or an elevated reticulocyte count, because reticulocytes have higher enzyme activity. **Pyruvate kinase (PK) deficiency** is the 2nd most common RBC enzymopathy and may also be associated with neonatal jaundice and bizarre morphology featuring acanthocytes.

Red Blood Cell Production

RBC underproduction is also common in the neonate, particularly among preterm infants. Because of relative polycythemia and the physiologic right shift in the oxyhemoglobin dissociation curve, there is typically sufficient oxygen delivery to the tissues during the 1st weeks of postuterine life. The erythropoietic drive is thus limited, and active erythropoiesis does not commence until the 2nd mo of life. This physiologic underproduction of erythrocytes appears to be prolonged in preterm infants and results in a steeper physiologic nadir referred to as **anemia of prematurity** . Anemia of prematurity is exacerbated by acute illness, frequent phlebotomy, and other comorbidities observed in premature infants.

In addition to physiologic underproduction of erythrocytes, several acquired and congenital conditions may further suppress bone marrow production (see Table 124.2). Both bacterial and viral infections may result in suppression of erythropoiesis and contribute to neonatal anemia; infectious etiologies are numerous but TORCH infections and parvovirus B19 are the most common. Tables 124.1 and 124.2 list congenital causes of neonatal anemia, including congenital leukemia, bone marrow failure syndromes (Fanconi anemia, Schwachman-Diamond syndrome), Diamond-Blackfan anemia), and variants in γ-globin, β-globin, or α-globin. Notably, common β-hemoglobinopathies such as sickle cell disease and thalassemia do not present in the neonatal period, as a result of the protective effect of high levels of HbF in the first few months of life.

Treatment Options for Neonatal Anemia

Packed Red Blood Cell Transfusions

Treatment of neonatal anemia by blood transfusion depends on the severity of symptoms, the hemoglobin concentration, and the presence of comorbidities (e.g., bronchopulmonary dysplasia, cyanotic congenital heart disease, respiratory distress syndrome) that interfere with oxygen delivery. The benefits of blood transfusion should be balanced against its risks, which include hemolytic and nonhemolytic reactions; exposure to blood product preservatives and toxins; volume overload; possible increased risk of retinopathy of prematurity and necrotizing enterocolitis; graft-versus-host reaction; and transfusion-acquired infections such as cytomegalovirus (CMV), HIV, parvovirus, and hepatitis B and C (see Chapter 501). The frequency of transfusion for neonates in the NICU is high, particularly among premature and very-low-birthweight (VLBW) infants.

Few studies have evaluated the efficacy or safety of specific hemoglobin/hematocrit thresholds, but a Cochrane review summarized the available evidence and proposed guidelines for transfusion of VLBW infants. The review identified 4 trials comparing *restrictive* (lower) to *liberal* (higher) hemoglobin thresholds. There were no statistically significant differences in death or serious morbidity, and the restrictive thresholds modestly reduced exposure to blood products. Evidence was inconclusive, however, regarding the effectiveness of either threshold in optimizing long-term neurocognitive outcomes. The proposed guideline for the transfusion of neonates was based primarily on postnatal age and the presence or absence of respiratory support (Table 124.4). In addition to these factors, transfusion should be considered for infants with acute blood loss (>20%) or significant hemolysis, as well as before surgery. With no similar evidence-based guidelines for term infants, transfusion should be based on hemodynamic stability, respiratory status, overall clinical condition, and laboratory values.

Table 124.4

Suggested Transfusion Thresholds

POSTNATAL AGE	PRESENCE OF RESPIRATORY SUPPORT	ABSENCE OF RESPIRATORY SUPPORT
	Hemoglobin Concentration, g/dL (Hematocrit %)	
Week 1	11.5 (35%)	10.0 (30%)

Week 2	10.0 (30%)	8.5 (25%)
Week 3	8.5 (25%)	7.5 (23%)

When the decision to transfuse has been made, the appropriate blood product should be selected and a safe volume of blood should be transfused at a safe rate. It is important to transfuse packed erythrocytes (PRBCs) to all neonates in the form of **leukocyte-reduced** or **CMV-seronegative** PRBCs, to reduce the risk of CMV transmission. **Irradiation** of PRBCs removes the risk of transfusion-associated graft-versus-host disease (GVHD) *but does not eliminate* the risk of CMV transmission. The volume of transfusion should achieve the intended therapeutic goal while limiting blood product exposure. Typical transfusion protocols choose a transfusion volume ranging from 10-20 mL/kg. There are no clear data to favor a specific amount, but lower volumes exposure infants to risks unnecessarily while higher volumes may cause fluid overload. One logical goal is to target a specific goal hemoglobin (Hb) concentration. The following commonly used shorthand equation can provide a good estimate of required blood volume, which usually results in a transfusion volume within the 10-20 mL/kg range:

$$\text{PRBC transfusion volume} = (\text{Desired Hb [g/dL]} - \text{Actual Hb}) \\ \times \text{Weight (kg)} \times 3$$

Transfusion of PRBCs is typically delivered at a rate of 3-5 mL/kg/hr, with a slower rate preferred for very small, acutely ill infants with a tenuous fluid status. Each transfusion should be completed within 4 hours.

Erythropoietin

Because of the low physiologic levels of erythropoietin in neonates, the role of recombinant human erythropoietin (**rhEPO**) has been investigated for the treatment of anemia in neonates, particularly VLBW infants. A Cochrane review documented that rhEPO is associated with a significant reduction in the number of blood transfusions per infant, but also a significantly increased risk of retinopathy of prematurity. There were no differences in mortality or other neonatal morbidities among infants who did or did not receive rhEPO. Because of these limited benefits and potential serious risks of early rhEPO therapy, there is currently no strong indication for the routine use of rhEPO in infants with anemia, although it should be considered in individual settings.

Hemolytic Disease of the Fetus and Newborn

Omar Niss, Russell E. Ware

Keywords

exchange transfusion
fetal anemia
hemolytic anemia
intrauterine transfusion
Rh alloimmunization

Hemolytic disease of the fetus and newborn (**HDFN**), also known as **erythroblastosis fetalis** , is caused by the transplacental passage of maternal antibodies directed against paternally derived red blood cell (RBC) antigens, which causes increased RBC destruction (hemolysis) in the infant. HDFN is an important cause of anemia and jaundice in newborn infants, and early recognition and diagnosis are crucial for proper management. Although more than 60 different RBC antigens are capable of eliciting a maternal antibody response, clinically significant disease is associated primarily with incompatibility of **ABO blood groups** and the **RhD antigen** . Less frequently, hemolytic disease may be caused by differences in other antigens of the Rh system or by other RBC antigens such as C^W , C^X , D^U , K (**Kell**), M, Duffy, S, P, MNS, Xg, Lutheran, Diego, and Kidd. Notably, anti-Lewis maternal antibodies rarely cause HDFN.

Hemolytic Disease Caused by Rh Incompatibility

The Rh antigenic determinants are genetically transmitted from each parent and determine the Rh blood type by directing the production of Rh proteins (C, c, D, E, and e) on the RBC surface. **RhD** is responsible for 90% of HDFN cases involving the Rh antigen system, but other Rh antigens (especially E and c) also can be etiologic.

Pathogenesis

Alloimmune hemolytic disease from RhD antigen incompatibility is approximately 3 times more common among whites than among blacks, because of differences in Rh allele frequency. Approximately 85% of Caucasians express RhD antigen (**Rh-positive**), whereas 99% of persons from Africa or Asia are Rh-positive. When Rh-positive blood is infused into an unsensitized Rh-negative woman, antibody formation against the mismatched Rh antigen is induced in the recipient. This can occur through transfusion, but the typical scenario is when small quantities (usually >1 mL) of Rh-positive fetal blood, inherited from an Rh-positive father, enter the maternal circulation during pregnancy, through spontaneous or induced abortion, or at delivery. Once sensitization has occurred, considerably smaller doses of antigen can stimulate an increase in antibody titer. Initially, a rise in immunoglobulin (Ig) M antibody occurs, which is later replaced by IgG antibody. Unlike IgM antibodies, IgG readily crosses the placenta to cause hemolytic manifestations.

HDFN requires Rh-antigen mismatch between the infant and the mother, with prior maternal exposure to RBCs expressing the cognate antigen. Hemolytic disease rarely occurs during a first pregnancy because transfusion of Rh-positive fetal blood into an Rh-negative mother usually occurs near the time of delivery, which is too late for the mother to become sensitized and transmit antibody to that infant before delivery. However, fetal-to-maternal transfusion is thought to occur in only 50% of pregnancies, so Rh incompatibility does not always lead to

Rh sensitization. Another important factor is the allele frequency of the RhD antigen because homozygous Rh-positive fathers must transmit the antigen to the fetus, whereas heterozygous fathers have only a 50% chance of having Rh-positive offspring. A smaller family size also reduces the risk of sensitization.

The outcome for Rh-incompatible fetuses varies greatly, depending on the characteristics of both the RBC antigen and the maternal antibodies. Not all maternal-fetal antigen incompatibility leads to alloimmunization and hemolysis. Factors that affect the outcome of antigen-positive fetuses include differential immunogenicity of blood group antigens (RhD antigen being the most immunogenic), a threshold effect of fetomaternal transfusions (a certain amount of the immunizing blood cell antigen is required to induce the maternal immune response), the type of antibody response (IgG antibodies are more efficiently transferred across the placenta to the fetus), and differences in the maternal immune response, presumably related to differences in the efficiency of antigen presentation by various major histocompatibility complex (MHC) loci.

Notably, when the mother and fetus are also ABO incompatible, the Rh-negative mother is partially protected against sensitization due to rapid removal of the fetal Rh-positive cells by maternal isohemagglutinins (preexisting IgM anti-A or anti-B antibodies that do not cross the placenta). Once a mother has been sensitized, all subsequent infants expressing that cognate antigen on RBCs are at risk for HDFN. The severity of Rh illness typically worsens with successive pregnancies because of repeated immune stimulation. The likelihood that Rh sensitization affects a mother's childbearing potential argues urgently for the prevention of sensitization. The injection of anti-Rh immune globulin (RhoGAM) into the Rh-negative mother, both during pregnancy and immediately after the delivery of each Rh-positive infant, reduces HDFN caused by RhD alloimmunization.

Clinical Manifestations

The severity of HDFN is variable, ranging from only laboratory evidence of mild hemolysis to severe anemia with compensatory hyperplasia of erythropoietic tissues, leading to massive enlargement of the liver and spleen. When hemolysis exceeds the compensatory capacity of the hematopoietic system, profound anemia occurs and results in pallor, signs of cardiac decompensation (cardiomegaly, respiratory distress), massive anasarca, and circulatory collapse. This clinical picture of excessive abnormal fluid in 2 or more fetal compartments (skin, pleura, pericardium, placenta, peritoneum, amniotic fluid), termed **hydrops fetalis** , frequently results in death in utero or shortly after birth.

The severity of hydrops is related to the level of anemia and the degree of edema caused by a reduction in serum albumin (oncotic pressure), which is partly a result of hepatic congestion and hepatic dysfunction. Alternatively, heart failure may increase right-sided heart pressure, with the subsequent development of edema and ascites. Failure to initiate spontaneous effective ventilation because of pulmonary edema or bilateral pleural effusions results in birth asphyxia. After successful resuscitation, severe respiratory distress may develop. Petechiae, purpura, and thrombocytopenia may also be present in severe cases, as a result of decreased platelet production or the presence of concurrent disseminated intravascular coagulation (DIC). Fortunately, with the routine use of RhoGAM to prevent Rh sensitization, *hydrops caused by HDFN has become rare and is more frequently encountered in nonhemolytic conditions.*

Jaundice may be absent at birth because of effective placental clearance of lipid-soluble unconjugated bilirubin, but in severe cases, bilirubin pigments can stain the amniotic fluid, cord, and vernix caseosa. *Jaundice is generally evident in the initial 24 hr of life, which is always pathologic,* because the infant's bilirubin-conjugating and excretory systems are unable to cope with the load resulting from massive hemolysis. Indirect-reacting bilirubin accumulates postnatally and may rapidly reach extremely high levels and present a significant risk of bilirubin encephalopathy (kernicterus). The risk of development of kernicterus from HDFN is greater than from comparable nonhemolytic hyperbilirubinemia, although the risk in an individual patient may be affected by other complications such as hypoxia or acidosis. **Hypoglycemia** also occurs in infants with severe HDFN and may be related to hyperinsulinism and hypertrophy of the pancreatic islet cells in these infants.

Infants with signs of severe disease in utero (hydrops, severe fetal anemia) may benefit from **intrauterine transfusion** , given either directly into the peritoneum or through the umbilical cord. Such infants usually have very high (but extremely variable) cord levels of bilirubin, reflecting the severity of the hemolysis and its effects on hepatic function. Infants treated with transfusions in utero may also have a benign postnatal course if the anemia and hydrops resolve before birth. Ongoing hemolysis can be masked by the previous intrauterine transfusion.

Laboratory Data

Before treatment, the direct antiglobulin test (DAT), or Coombs test, is positive, and anemia is generally present. The cord blood hemoglobin content varies and is usually proportional to the severity of the disease. In cases of hydrops fetalis, the hemoglobin concentration may be as low as 3-4 g/dL. Alternatively, despite hemolysis, hemoglobin may be within the normal range because of compensatory bone marrow and extramedullary hematopoiesis. The initial *reticulocyte count* is increased, another abnormal finding at birth, and the peripheral blood smear typically shows polychromasia with a marked increase in nucleated RBCs. The white blood cell count is usually normal but may be elevated, and thrombocytopenia develops in severe cases. Cord bilirubin levels are generally between 3 and 5 mg/dL; the *direct-reacting (conjugated) bilirubin* content may also be elevated (from cholestasis), especially if there was a previous intrauterine transfusion. Indirect-reacting bilirubin content rises rapidly to high levels in the 1st 6-12 hr of life.

After intrauterine transfusions, cord blood may show a normal hemoglobin concentration, *negative* DAT result, predominantly Rh-negative adult RBCs, low/normal reticulocyte count, and relatively normal blood smear findings.

Diagnosis

Definitive diagnosis of HDFN requires demonstration of blood group incompatibility between mother and infant and corresponding maternal antibody bound to the infant's RBCs.

Antenatal Diagnosis

Without proof of immunoglobulin prophylaxis, any Rh-negative women with previous pregnancy or abortion, prior exposure to transfused blood, or receipt of an organ transplant should be considered at risk for Rh sensitization. During pregnancy, the expectant parents should have blood tested for potential incompatibility, particularly for ABO and Rh antigens. If RhD incompatible, the maternal titer of IgG antibodies to the RhD antigen should be measured early in pregnancy. Paternal blood can be tested to determine the fetal risk of inheriting the cognate antigen, typically either 50% or 100% depending on whether the father is heterozygous or homozygous for the antigen. However, paternal serologic testing alone is not fully accurate to predict the zygosity of RhD antigen, and molecular genotyping is recommended for both parents in this setting.

Fetal RBC genotyping provides an accurate prediction for the development of HDFN in sensitized mothers. Fetal Rh status is available by isolating fetal cells or fetal DNA (plasma) from the maternal circulation, which is replacing the more invasive and risky fetal amniocyte testing by amniocentesis and chorionic villus sampling methods. The presence of elevated antibody titers or rising titers increases the risk of the baby developing severe HDFN.

Although maternal antibody titers are often used to predict the risk of HDFN, there is a poor correlation between the anti-D titer level and the severity of the disease, especially in subsequent pregnancies. If an Rh-negative mother is found to have RhD antibody titers of ≥1 : 16 (15 IU/mL in Europe) at any time during a subsequent pregnancy, the severity of fetal anemia should be monitored by Doppler ultrasonography (US) of the middle cerebral artery (MCA) and then percutaneous umbilical blood sampling (PUBS) if indicated (Fig. 124.7). If the mother has a history of a previously affected infant or a stillbirth, an Rh-positive infant is usually equally or more severely affected than the previous infant, and the severity of disease in the fetus should be monitored starting at 16-24 wk of gestation.

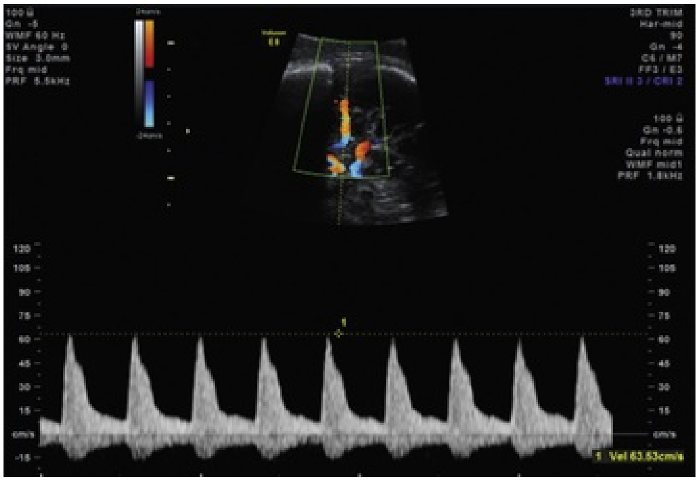

FIG. 124.7 **Middle cerebral artery (MCA) Doppler study of elevated peak systolic velocity (PSV). MCA-PSV can predict fetal anemia with sufficient accuracy to determine management, including the need for intrauterine transfusion or, in the mid- to late third trimester, early delivery. Fetal hemoglobin is typically measured at the start and end of intravascular transfusion to validate the prediction from MCA-PSV results. The reliability of MCA-PSV can decrease after intrauterine transfusion because of the altered rheostatic characteristics of transfused adult blood. This is now the method of choice for detecting fetal anemia. (From Liley HG, Gardener G, Lopriore E, Smits-Wintjens V: Immune hemolytic disease. In Orkin SH, Nathan DG, Ginsburg D, et al,**

editors: *Nathan and Oski's hematology and oncology of infancy and childhood,* ed 8, Philadelphia, 2015, Elsevier, Fig 3-6.)

Pregnancies at risk for HDFN should be managed by maternal-fetal specialists. Assessment of the fetus includes US and PUBS. Real-time US is used to detect signs of hydrops (skin or scalp edema, pleural or pericardial effusions, and ascites) and fetal heart rate monitoring. Early US signs of hydrops include organomegaly (liver, spleen, heart), the double–bowel wall sign (bowel edema), and placental thickening. Progression to polyhydramnios, ascites, pleural or pericardial effusions, and skin or scalp edema may then follow. Extramedullary hematopoiesis and hepatic congestion compress the intrahepatic vessels and produce venous stasis with portal hypertension, hepatocellular dysfunction, and decreased albumin synthesis. *Hydrops is typically present when fetal hemoglobin level is <5 g/dL.* Hydrops is also frequently seen with a fetal hemoglobin level <7 g/dL, and in some cases between 7 and 9 g/dL.

Doppler US assesses fetal distress by demonstrating increased vascular resistance in fetal arteries, especially in the infant MCA (see Fig. 124.7). In fetuses without hydrops, moderate to severe anemia can be detected noninvasively by demonstration of an increase in the peak velocity of systolic blood flow in the MCA. The velocity of blood flow correlates with the severity of the anemia and therefore can be used as a noninvasive surrogate marker that can be followed. In pregnancies with moderate-severe fetal anemia (demonstrated by high cerebral velocities) or US evidence of hemolysis (hepatosplenomegaly), early or late hydrops, or fetal distress, further and more direct assessment of fetal hemolysis should be performed.

Amniocentesis was the classic method for assessing fetal hemolysis, by measuring changes in optical density of the amniotic fluid with serial determination of bilirubin levels. However, amniocentesis is an invasive procedure with risks to both the fetus and the mother, including fetal death, bleeding, bradycardia, worsening of alloimmunization, premature rupture of membranes, preterm labor, and chorioamnionitis. Doppler measurement of the peak velocity of systolic blood flow in the MCA has essentially replaced invasive testing in the management of HDFN.

PUBS is the standard approach to the assessment of the fetus if Doppler and real-time US findings suggest that the fetus has moderate to severe anemia. PUBS is performed to determine fetal hemoglobin levels and to transfuse packed RBCs into fetuses with serious fetal anemia (hematocrit <30%) who are immature and not suitable for delivery.

Postnatal Diagnosis

Immediately after the birth of an infant to an Rh-negative woman, or any infant with the appearance of hydrops, blood from the umbilical cord or the infant should be tested for ABO blood group, Rh type, hematocrit and hemoglobin, reticulocyte count, serum bilirubin, and the DAT. A positive DAT result indicates the presence of maternal antibody on the infant RBC, and the incompatible RBC antigen must be identified. The infant's cells can be investigated, but maternal serum should also be screened for RBC antibodies using commercially available panels. These tests not only help establish the diagnosis, but also enable selection of compatible blood for exchange transfusion of the infant, if necessary. The DAT is usually strongly positive in clinically affected infants and may remain so for weeks or even several months.

Treatment

The main goals of therapy for HDFN are (1) to prevent intrauterine or extrauterine death from severe anemia and hypoxia, (2) to prevent neurodevelopmental damage in affected children, and (3) to avoid neurotoxicity from hyperbilirubinemia.

Treatment of the Unborn Fetus

Survival of severely affected fetuses has improved with the advent of fetal US to assess the need for in utero transfusion. Intravascular (umbilical vein) transfusion of packed erythrocytes (PRBCs) is the preferred treatment of choice for fetal anemia, although intrauterine transfusion into the fetal peritoneal cavity is also effective. Hydrops or fetal anemia (hematocrit <30%) is an indication for umbilical vein transfusion in infants with pulmonary immaturity.

Fetal transfusion is facilitated by maternal and hence fetal sedation. PRBCs are slowly infused after being cross-matched against the mother's serum. The erythrocytes should be selected from a donor who is group O, negative for the mismatched antigen (e.g., RhD-negative), and CMV-negative. The blood should also be leukocyte-reduced to reduce the risk of allergic and nonhemolytic reactions and irradiated to avoid transfusion-associated GVHD. Some centers use extended group matching (e.g., RhCE, Kell) to decrease the risk of additional maternal antibody formation. Transfusions should achieve a posttransfusion hematocrit of 45–55% and can be repeated every 3-5 wk.

Intrauterine transfusions ameliorate neurologic complications in many fetuses; however, those with severe hydrops are at risk for cerebral palsy, developmental delay, and deafness. The overall survival rate after intrauterine transfusions is 89%, and the complication rate is 1–3%. In contrast, the outcome after cordocentesis and intrauterine transfusions performed earlier, such as the second trimester, is poor. Complications include rupture of the membranes and preterm delivery, infection, fetal distress requiring emergency cesarean delivery, and perinatal death. Maternal plasma exchange and intravenous immune globulin (IVIG) have been used as adjunctive therapies in women with prior severe HDFN, but there is limited evidence to support their routine use. Indications for early delivery include pulmonary maturity, fetal distress, complications of PUBS, and 35-37 wk of gestation. Careful antenatal care, including intrauterine transfusions, has decreased the need for postdelivery exchange transfusion.

Treatment of the Liveborn Infant

The birth should be attended by a physician skilled in neonatal resuscitation. Fresh, leukoreduced, and irradiated group O and Rh-negative blood, which has been cross-matched against maternal serum, should be immediately available. If clinical signs of **severe hemolytic anemia** (pallor, hepatosplenomegaly, edema, petechiae, ascites) are evident at birth, immediate resuscitation and supportive therapy, temperature stabilization, and monitoring before proceeding with exchange transfusion may save severely affected infants. Such therapy should include a small transfusion of compatible PRBCs to correct anemia; volume expansion for hypotension, especially in those with hydrops; correction of acidosis with 1-2 mEq/kg of sodium bicarbonate; and assisted ventilation for respiratory failure. Infants with HDFN should be closely monitored with frequent hemoglobin and bilirubin testing to determine their need for phototherapy, simple transfusion, or exchange transfusion.

Exchange Transfusion

The decision to proceed with an immediate full or partial exchange transfusion should be based on the infant's clinical condition at birth, with a judgment specifically regarding the likelihood of the infant rapidly developing a dangerous degree of anemia or hyperbilirubinemia. Cord hemoglobin value of ≤10 g/dL or bilirubin concentration ≥5 mg/dL suggest severe hemolysis, but neither consistently predicts the need for exchange transfusion. Some physicians consider previous kernicterus or severe HDFN in a sibling, reticulocyte counts >15%, and prematurity to be additional factors supporting a decision for early exchange transfusion (see Chapters 123.3 and 123.4).

The hemoglobin concentration and serum bilirubin level should be measured at 4-6 hr intervals initially, with extension to longer intervals as the rate of change diminishes. The decision to perform an exchange transfusion is often based on the likelihood that the bilirubin levels, which can be plotted against postnatal hours of life, will reach dangerous levels (see Fig. 123.14 and Table 123.7 in Chapter 123). *Term infants with bilirubin levels ≥20 mg/dL have an increased risk of kernicterus.* Simple transfusions of ABO-compatible, Rh-negative, leukoreduced, and irradiated RBCs may be necessary to correct anemia up to 6-8 wk of age, after which the infant's own erythropoiesis can be expected to overcome any lingering hemolysis. Weekly determinations of hemoglobin values should be performed until the physiologic nadir is passed and a spontaneous rise has been demonstrated.

Careful monitoring of the serum bilirubin level is essential until a decline has been documented in the absence of phototherapy (see Chapter 123.3). Even then, an occasional infant, particularly if premature, may experience a significant rebound in serum bilirubin as late as the 7th day of life. Attempts to predict dangerously high levels of bilirubin based on levels exceeding 6 mg/dL in the 1st 6 hr of life, or 10 mg/dL in the 2nd 6 hr of life, or on increasing rates exceeding 0.5-1.0 mg/dL/hr, are often quoted but not necessarily reliable.

Procedure

The actual exchange transfusion can be performed most easily through an umbilical vein catheter or through peripheral arterial (remove) and venous (return) lines. The exchange should be carried out over 45-60 min and involves serial removal of 15-20 mL aliquots of infant blood (term infant), alternating with infusion of an equivalent volume of donor blood. Smaller, 5-10 mL aliquots may be better tolerated by sick or premature infants. The goal should be an isovolemic exchange of approximately 2 blood volumes of the infant (2 × 100 mL/kg) to achieve 90% replacement of fetal RBCs and 50% removal of bilirubin.

Blood for exchange transfusion should be as fresh as possible. Standard anticoagulants and preservatives such as citrate-phosphate-dextrose-adenine solution can be used. Blood selection is similar to that of intrauterine transfusions, typically leukoreduced and irradiated erythrocytes from a group O and Rh-negative donor. Although the blood should be negative for the mismatched Rh antigen, a complete crossmatch should be performed before transfusion. Packed erythrocytes should be reconstituted with fresh-frozen plasma to a hematocrit of about 40% before the procedure. Blood should be gradually warmed and maintained at a temperature between 35°C and 37°C throughout the exchange transfusion. It should be kept well mixed by gentle squeezing or agitation of the bag to avoid sedimentation. The infant's stomach should be emptied before transfusion to prevent aspiration, and body temperature should be maintained and vital signs monitored. A competent assistant should be present to help monitor, tally the volume of blood exchanged, and perform emergency procedures.

Infants with acidosis and hypoxia from respiratory distress, sepsis, or shock may be further compromised by the significant exposure to citrate, which provides both an acute acid load (pH 7.0-7.2) and calcium binding. The subsequent metabolism of citrate may later result in metabolic alkalosis. Fresh heparinized blood avoids this problem but is not readily available in most settings. During the exchange transfusion, blood pH and PaO_2 should be serially monitored to avoid acidosis and hypoxia. Symptomatic hypoglycemia may occur before, during, or after an exchange transfusion in moderately to severely affected infants. Additional acute complications, noted in 5–10% of infants, include transient bradycardia with or without calcium infusion, cyanosis, transient vasospasm, thrombosis, thrombocytopenia, apnea with bradycardia requiring resuscitation, and death. Infectious risks include CMV, HIV, and hepatitis. Necrotizing enterocolitis is a rare complication of exchange transfusion for HDFN.

There is a risk of death from an exchange transfusion, even when performed by an experienced physician team, estimated at 3 per 1,000 procedures. With the fortunate decline of this procedure because of phototherapy and prevention of sensitization, experience with such procedures and physician competence are diminishing, and exchange should be performed only at experienced neonatal referral centers.

After exchange transfusion, the bilirubin level must be measured at frequent intervals (every 4-8 hr) because the serum value may rebound 40–50% because of reequilibration and ongoing production. Repeated exchange transfusions are occasionally necessary, with the primary aim of keeping the indirect bilirubin fraction from exceeding dangerous levels indicated in Table 123.7 (see Chapter

123) for preterm infants and 20 mg/dL for term infants. Signs and symptoms suggestive of kernicterus are mandatory indications for exchange transfusion at any time.

Intravenous Immune Globulin

Because of its ability to interfere with immune-mediated clearance of antibody-sensitized RBCs, early administration of IVIG may be an effective therapeutic intervention for HDFN. IVIG can prevent immune hemolysis, lower peak serum bilirubin levels, shorten the duration of phototherapy, and reduce both length of hospitalization and need for exchange transfusion. However, IVIG does not effectively prevent anemia, which results from both immune-mediated RBC destruction and inadequate erythropoiesis. Consequently, simple transfusions are usually needed as an adjunct to IVIG therapy. An IVIG dose of 0.5-1 g/kg is typically used, but optimal dosing has not been established. Treated infants with blood groups A or B should be monitored for worsening hemolysis caused by anti-A or anti-B antibodies present in IVIG.

Late Complications

Infants with HDFN, including those who have had an intrauterine or postnatal exchange transfusion, must be observed carefully for the development of late anemia and cholestasis.

Late anemia , operationally defined as occurring after the 1st 4-6 wk of life, can result from either persistent hemolysis caused by circulating maternal alloantibodies or from effects on the bone marrow. **Late hyporegenerative anemia** in HDFN results from suppression of erythropoiesis, in part from the higher hemoglobin concentration provided through an intrauterine or exchange transfusion. Late hyporegenerative anemia can be distinguished from hemolytic anemia by a low or absent reticulocyte count and a normal bilirubin level. Infants should be monitored for symptoms and signs of anemia, including poor feeding, sleepiness, and poor growth. Hemoglobin and reticulocyte counts should be monitored weekly to determine the need for transfusion, until the marrow spontaneously recovers after several weeks to months. Neutropenia can also be observed during recovery from HDFN or in association with the late hyporegenerative anemia. In addition to transfusion, treatment with supplemental iron or erythropoietin may be helpful to accelerate marrow recovery.

Inspissated bile syndrome refers to the rare occurrence of persistent icterus in association with significant elevations in both direct and indirect bilirubin levels in infants with hemolytic disease. The cause is unclear, but jaundice clears spontaneously within a few weeks or months with conservative management. **Portal vein thrombosis** and portal hypertension may occur in children who have been subjected to exchange transfusion as newborn infants. It is probably associated with prolonged, traumatic, or septic umbilical vein catheterization.

Prevention of Rh Sensitization

The risk of initial sensitization of Rh-negative mothers has been reduced to less than 0.1% by the routine administration of Rh-immunoglobulin (RhoGAM) to all mothers at risk for Rh alloimmunization. The Rh-immunoglobulin product is administered to Rh-negative mothers as an intramuscular injection of 300 µg (1 mL) of human anti-D globulin within 72 hr of delivery of an Rh-positive infant. Additional clinical indications for RhoGAM administration include ectopic pregnancy, abdominal trauma during pregnancy, amniocentesis, chorionic villus biopsy, or abortion. This quantity of antibody is sufficient to eliminate approximately 10 mL of potentially antigenic fetal Rh-positive cells within the maternal circulation. Larger fetal-to-maternal transfers of blood will require proportionately more human anti-D globulin. RhoGAM administration provided at 28-32 wk of gestation and again at birth is more effective than a single dose.

It is also critical to use appropriately matched blood for all transfusions to Rh-negative girls and young women of childbearing years, including the use of group O, Rh-negative blood during emergencies, as a primary measure to prevent Rh antigen exposure. This approach, coupled with the use of anti-D immunoglobulin during/after pregnancy, plus improved methods of detecting maternal sensitization and measuring the extent of fetal-to-maternal transfusion, have dramatically decreased the incidence and severity of HDFN in developed countries. In addition, the use of fewer obstetric procedures that increase the risk of fetal-to-maternal bleeding should further reduce the incidence of this disorder. However, because serologic testing does not always accurately predict RhD type, since there are now well-recognized weak and partial RhD antigens, the use of fetal RhD genotyping will better guide appropriate use of Rh-immunoglobulin therapy in Rh-negative women.

Hemolytic Disease Caused by Blood Group A and B Incompatibility

Although ABO incompatibility is the most common cause of HDFN, this form is usually much milder than Rh disease and rarely requires aggressive clinical management or therapeutic intervention. Approximately 20% of live births are at theoretical risk for immune-mediated hemolysis based on ABO mismatch, most often the mother being group O and the infant either group A or B. Less often, the mother will be group A and the infant group B, or vice versa.

However, clinical manifestations of hemolysis develop in only 1–10% of at-risk infants, primarily because naturally occurring maternal antibodies against ABO blood group antigens are almost exclusively IgM and therefore do not cross the placenta. Some group O mothers will produce IgG antibodies against blood group A or B antigens, and these can cross the placenta and cause immune-mediated hemolysis. For example, an A-O incompatibility can cause hemolysis even in a firstborn infant, if the mother (group O) produces some anti-A IgG antibodies. A 2nd factor that accounts for the lower-than-predicted incidence of severe ABO hemolytic disease is the relatively low antigen frequency and expression on the RBC of the fetus and newborn infant. With few strong binding sites available for the maternal antibodies to bind, there is less hemolysis.

Clinical Manifestations

Most cases of ABO incompatibility are mild, with jaundice the only clinical manifestation. The infant is not generally affected at birth but will develop jaundice in the 1st 24 hr, which is always abnormal. Pallor and hepatosplenomegaly are not present, and the development of hydrops fetalis or kernicterus is extremely rare.

Diagnosis

A presumptive diagnosis is based on the presence of serologic ABO incompatibility between the mother and infant, plus a weakly to moderately positive DAT result. Hyperbilirubinemia is often the main laboratory abnormality. In 10–20% of affected infants, the unconjugated serum bilirubin level may reach 20 mg/dL or more unless phototherapy is administered. Usually the infant has mild anemia and reticulocytosis; the peripheral blood smear may show polychromasia, nucleated RBCs, and spherocytes. However, the persistence of hemolytic anemia or spherocytosis beyond 2 wk should suggest an alternative diagnosis, such as hereditary (congenital) spherocytosis (see Fig. 124.6).

Treatment

Phototherapy may be effective in lowering serum bilirubin levels (see Chapter 123.4). In severe cases, IVIG administration can be helpful by reducing the rate of hemolysis and the need for exchange transfusion. Exchange transfusions with group O and Rh-compatible blood type may be needed in some cases to correct dangerous degrees of anemia or hyperbilirubinemia. Indications for this procedure are similar to those previously described for hemolytic disease caused by Rh incompatibility . Some infants with ABO hemolytic disease may require transfusion of PRBC at several weeks of age because of hyporegenerative or slowly progressive anemia. *Postdischarge monitoring of hemoglobin or hematocrit is essential in newborns with ABO hemolytic disease.*

Other Forms of Hemolytic Disease

Blood group incompatibilities other than Rh or ABO account for <5% of HDFN. The pathogenesis of hemolytic disease in this setting is similar, because of other RBC antigens that are mismatched between mother and infant. The likelihood of encountering mismatches for minor antigen mismatches relates to their frequency in the population, their density on the RBC surface, their immunogenicity in the mother, and the index of suspicion. Minor RBC antigen mismatch (especially on Kell group) is emerging as a common cause of HDFN in the developed countries where anti-D immunoglobulin is routinely used. In all cases, the maternal serum should have RBC alloantibodies identified that react against the infant (and paternal) erythrocytes. In addition, the infant's DAT result is invariably positive, and elution techniques can identify the antigen specificity.

Common RBC antigens that can lead to clinically relevant incompatibility include those in the Kell, Duffy, and MNS blood groups. Notably, maternal anti-Lewis antibodies do not lead to HDFN because they are IgM and do not cross the placenta, and Lewis antigens are poorly expressed on fetal erythrocytes. **Kell** is a particularly dangerous incompatibility because the severity of the hemolytic anemia is difficult to predict based on previous obstetric history, amniotic fluid bilirubin determinants, or maternal antibody titer. Kell-alloimmunized infants often have inappropriately low numbers of circulating reticulocytes caused by erythroid suppression, and even low maternal titers of anti-Kell antibodies may cause significant hypoproliferative anemia. Table 124.5 summarizes the clinical characteristics of hemolytic disease caused by Rh, ABO, and Kell antigen systems. There are no specific pharmacologic therapies available to prevent sensitization caused by any blood group other than RhD. As with cases of Rh and ABO incompatibility, exchange transfusion may be indicated for severe hyperbilirubinemia or severe anemia in infants with HDFN caused by minor antigen incompatibility.

Table 124.5

Hemolytic Disease of the Fetus and Newborn

	Rh	**ABO**	**KELL**
BLOOD GROUPS			
Mother	Rh-negative	O (occasionally B)	K1-negative
Infant	Rh-positive (D is most common)	A (sometimes B)	K1-positive
CLINICAL FEATURES			
Occurrence in firstborn	5%	40–50%	Rare
Severity in subsequent pregnancies:	Predictable	Difficult to predict	Somewhat predictable
Stillbirth/hydrops	Frequent (less with Rh-immunoglobulin use)	Rare	10%
Severe anemia	Frequent	Rare	Frequent
Jaundice	Prominent, severe	Mild-moderate	Mild
LABORATORY TESTS			
Direct antiglobulin test (infant)	Positive	Positive or negative	Positive or negative
Reticulocyte count	Elevated	Elevated	Variable
Red blood cell (RBC) antibodies (mother)	Usually detectable Antibody titers may help predict severity of fetal disease.	May not be detectable Antibody titers may not correlate with fetal disease.	Usually detectable Antibody titers may not correlate with fetal disease; fetus can be affected at titers lower than for Rh-mediated hemolysis.

Neonatal Polycythemia

Omar Niss, Russell E. Ware

Keywords

hyperviscosity
polycythemia

Neonatal polycythemia is defined as a central hemoglobin or hematocrit (Hct) exceeding 2 standard deviations (SD) above the normal value for gestational and postnatal age. A full-term infant is therefore considered to have polycythemia when the hemoglobin concentration is ≥22 g/dL or Hct is ≥65%. Measuring the *central hemoglobin* using an automated blood counter is important because both peripheral (heelstick) and capillary tube microcentrifugation yield higher Hct values than central values, by up to 15%. Timing is also important; because of fluid shifts in the newborn period, Hct peaks during the 1st 2-3 hr of life. The frequency of neonatal polycythemia is also increased for births at higher altitudes (5% at high altitude vs 1–2% at sea level). Polycythemia predisposes to **hyperviscosity** (not clinically measurable), which may be the primary issue. When Hct is >65%, hyperviscosity may rapidly increase.

Etiologies of neonatal polycythemia are numerous but can be grouped into two broad categories based on passive RBC transfusion into the fetus and increased intrauterine erythropoiesis. Causes of passive fetal RBC transfusion include delayed clamping of the umbilical cord (most common cause in term infants), twin-twin transfusion for the recipient, and rarely, maternal-fetal transfusions. In contrast, neonatal polycythemia secondary to increased fetal erythropoiesis has many causes, including postmaturity (3%) vs term (1–2%) infants; small-for-gestational-age (8%) or large-for-gestational-age (3%) vs average-for-gestational-age (1–2%) infants; infants of diabetic mothers; infants with trisomy 13, 18, or 21; adrenogenital syndrome; neonatal Graves disease;

hypothyroidism; infants of hypertensive mothers or those taking propranolol; and Beckwith-Wiedemann syndrome. Although the pathogenesis of increased erythropoiesis is not always fully understood, infants of diabetic or hypertensive mothers and those with growth restriction may have been exposed to chronic fetal hypoxia, which stimulates erythropoietin production and increases RBC production.

Signs and symptoms of polycythemia can result from hyperviscosity (sluggish blood flow causing decreased tissue perfusion) or metabolic disturbances, or both. Most polycythemic infants are asymptomatic. Symptoms often appear in the 1st few hr of life but can be delayed by up to 2-3 days. Symptoms include irritability, lethargy, tachypnea, respiratory distress, cyanosis, feeding disturbances, hyperbilirubinemia, hypoglycemia, and thrombocytopenia. Severe complications include seizures, stroke, pulmonary hypertension, necrotizing enterocolitis (NEC), renal vein thrombosis, and renal failure. Because most infants are asymptomatic and these symptoms overlap with many neonatal conditions, other respiratory, cardiovascular, and neurologic diseases should be ruled out. Dehydration should also always be considered as a cause. Whether these symptoms are truly caused by, or just associated with, polycythemia is undetermined. Hyperviscosity in infancy may be accentuated because neonatal RBCs are large and have decreased deformability, which together predispose to stasis in the microcirculation.

The **treatment** of polycythemia varies among centers and is often based primarily on local expert opinion. A capillary Hct >65% should always be confirmed with a venous sample and dehydration should be treated. All polycythemic infants should be closely monitored for intake and output, and blood glucose and bilirubin levels should be closely followed. Asymptomatic infants whose central Hct is 60–70% can be monitored closely and hydrated with adequate enteral intake or administration of intravenous (IV) fluids. Treatment of symptomatic polycythemic newborns is not well defined. A partial exchange transfusion (with normal saline) can be used in infants with severe polycythemia and symptoms of hyperviscosity and should be considered if the Hct is ≥70–75% and symptoms worsen despite aggressive IV hydration. Partial exchange transfusion lowers Hct and viscosity acutely and improves acute symptoms but may not affect long-term outcome in polycythemic infants.

Polycythemic infants treated with partial exchange transfusion may be at increased risk of NEC, and their long-term prognosis is unclear. Reported adverse outcomes include speech deficits, abnormal fine motor control, reduced

IQ, school problems, and other neurologic abnormalities. The underlying etiology (**chronic intrauterine hypoxia**) is likely the determinant of these outcomes rather than polycythemia itself. Most asymptomatic infants develop normally.

Hemorrhage in the Newborn Infant

Cristina Tarango, Russell E. Ware

Keywords

disseminated intravascular coagulation
DIC
hemorrhagic disease of the newborn
neonatal hemorrhage
phytonadione
PIVKA
vitamin K deficiency bleeding

Neonates have a unique hemostatic system that places them at high risk for hemorrhagic complications, especially in the presence of illness or other stress. Plasma levels of the vitamin K–dependent coagulation factors (II, VII, IX, X, protein C, protein S) and antithrombin are low at birth and do not reach adult ranges until approximately 6 mo of age. Thrombin generation and platelet function are also altered in normal newborns. Consequently, both congenital and acquired bleeding disorders that affect primary or secondary hemostasis can manifest in the newborn period. In general, hemorrhage in a *healthy* neonate suggests an inherited coagulation defect or immune-mediated thrombocytopenia, whereas bleeding symptoms in a *sick* neonate are more likely to reflect underproduction or consumption of coagulation factors and/or platelets. *Congenital hemorrhagic disorders such as hemophilia can present with bleeding in the newborn period.* Common acquired hemorrhagic disorders include vitamin K deficiency bleeding, disseminated intravascular coagulation (see Chapter 510), and immune-mediated thrombocytopenia (Chapter 511.9).

Vitamin K Deficiency Bleeding

Vitamin K deficiency bleeding, previously referred to as **hemorrhagic disease of the newborn** , results from transient but severe deficiencies in the vitamin K–dependent factors and is characterized by hemorrhage that is most frequently gastrointestinal, nasal, subgaleal, intracranial, or postcircumcision. Prodromal or warning signs (mild bleeding) may occur before serious intracranial hemorrhage. Laboratory testing reveals that both the prothrombin time (PT) and partial thromboplastin time are prolonged, and plasma levels of prothrombin (II) and factors VII, IX, and X are substantially decreased. The pathophysiology of this acquired hemorrhagic disorder results because vitamin K facilitates posttranscriptional carboxylation of factors II, VII, IX, and X, which is necessary for its full coagulation effects. In the absence of carboxylation, such factors form **PIVKA** (proteins induced in vitamin K absence), which have greatly reduced function; these can be measured and represent a sensitive marker for vitamin K status. In contrast, factors V and VIII, fibrinogen, bleeding time, clot retraction, and platelet count and function are normal for maturity.

Classically, *vitamin K deficiency bleeding occurs early in the newborn period,* typically between day 2 and 7 of life, and most often in exclusively breastfeeding infants who did not receive vitamin K prophylaxis at birth. Severe vitamin K deficiency is also more common in premature infants. This pathogenesis occurs from a lack of free vitamin K from the mother, coupled with absence of bacterial intestinal flora normally responsible for the synthesis of vitamin K. Breast milk is a poor source of vitamin K, which explains why hemorrhagic complications are more frequent in exclusively breastfed than in mixed-fed or formula-fed infants. This classic form of hemorrhagic disease of the newborn, which is responsive to (and entirely prevented by) exogenous vitamin K therapy, should be distinguished from rare congenital deficiencies of clotting factors that are unresponsive to vitamin K, which can occur in otherwise well-appearing infants (see Chapter 503).

Early-onset vitamin K deficiency bleeding (after birth but in 1st 24 hr) occurs if the mother has been treated chronically with certain drugs (e.g., anticoagulant warfarin, anticonvulsant phenytoin or phenobarbital, cholesterol-lowering medication) that interfere with vitamin K absorption or function. These infants can have severe bleeding, which is usually corrected promptly by vitamin K administration, although some have a poor or delayed response. If a mother is known to be receiving such drugs late in gestation, an infant PT should be measured using cord blood, and *the infant immediately given 1-2 mg of vitamin K intravenously.* If PT is greatly prolonged and fails to improve, or in the presence of significant hemorrhage, *10-15 mL/kg of fresh-frozen plasma should be administered.* In contrast, **late-onset** vitamin K deficiency bleeding (after 2 wk of life) is usually associated with conditions that feature malabsorption of the fat-soluble vitamin K, such as cystic fibrosis, neonatal hepatitis, or biliary atresia, and bleeding can be severe (Table 124.6).

Table 124.6

Vitamin K Deficiency Bleeding (Hemorrhagic Disease of the Newborn)

	EARLY-ONSET DISEASE	**CLASSIC DISEASE**	**LATE-ONSET DISEASE**
Age	0-24 hr	2-7 days	1-6 mo
Potential sites of hemorrhage	Cephalohematoma	Gastrointestinal	Intracranial
	Subgaleal	Ear-nose-throat-mucosal	Gastrointestinal
	Intracranial	Intracranial	Cutaneous
	Gastrointestinal	Post-circumcision	Ear-nose-throat-mucosal
	Umbilicus	Cutaneous	Injection sites
	Intraabdominal	Injection sites	Thoracic
Etiology/risks	Maternal drugs (phenobarbital, phenytoin, warfarin, rifampin, isoniazid) that interfere with vitamin K levels or absorption	Vitamin K deficiency Exclusive breastfeeding	Cholestasis: malabsorption of vitamin K (biliary atresia, cystic fibrosis, hepatitis)
	Inherited coagulopathy		Abetalipoprotein deficiency Idiopathic in Asian breastfed infants Warfarin ingestion
Prevention	Avoidance of high-risk medications Possibly antenatal vitamin K to treatment of mother (20 mg) before birth and postnatal administration to infant soon after birth	Prevented by parenteral vitamin K at birth Oral vitamin K regimens require repeated dosing.	Prevented by parenteral and high-dose oral vitamin K during periods of malabsorption or cholestasis
Incidence	Very rare	~2% if infant not given vitamin K soon after birth	Dependent on primary disease

Intramuscular (IM) administration of 1 mg of vitamin K (typically **phytonadione** , or vitamin K_1 , the only form of vitamin K available in the United States) soon after birth prevents the pathologic decrease in vitamin K–dependent factors in full-term infants. However, such vitamin K prophylaxis is not uniformly effective to prevent all hemorrhagic disease of the newborn, particularly in exclusively breastfed and premature infants. When an infant presents with hemorrhage, a slow IV infusion of 1-5 mg of vitamin K_1 is effective treatment and leads to improvement in coagulation defects and cessation of bleeding within a few hours. Serious bleeding, particularly in premature infants or those with liver disease, may require transfusion of fresh-frozen plasma or even whole blood. With prompt recognition and treatment, the mortality rate is low.

Decades of experience have demonstrated that the routine use of IM vitamin K for prophylaxis in the United States is safe, and specifically is *not* associated with an increased risk of childhood cancer or leukemia. Although multiple doses of oral vitamin K (1-2 mg at birth, again at discharge, and again at 3-4 wk of life) has been suggested as an alternative, *oral vitamin K is less effective* in preventing late-onset vitamin K deficiency bleeding and thus cannot be recommended for routine therapy. The IM route of vitamin K prophylaxis remains the method of choice.

Other forms of neonatal bleeding may be clinically indistinguishable from hemorrhagic disease of the newborn due to vitamin K deficiency, but they are neither prevented nor successfully treated with vitamin K. For example, an identical clinical presentation may also result from any congenital defect in blood coagulation factors (see Chapters 503 and 504). Hematomas, melena, and postcircumcision and umbilical cord bleeding may be present; up to 70% cases of hemophilia (factor VIII or IX deficiency) are clinically apparent in the newborn period. Treatment of these congenital deficiencies of coagulation factors requires specific factor replacement or fresh-frozen plasma if factor concentrate is not available.

Disseminated Intravascular Coagulopathy

Disseminated intravascular coagulation (**DIC**) in newborn infants results from consumption of circulating coagulation factors and platelets and therefore can present with either bleeding or thrombosis and usually with evidence of end-organ damage and increased mortality. Affected infants are often premature; their clinical course is frequently characterized by asphyxia, hypoxia, acidosis, shock, hemangiomas, or infection. Since DIC is a secondary event, the most effective treatment is directed at correcting the primary clinical problem, such as infection, to interrupt consumption of clotting factors and allow time to replace them (see Chapter 510). *Infants with DIC who have central nervous system hemorrhage, or other bleeding posing an immediate threat to life, should receive fresh-frozen plasma, vitamin K, and blood* if needed. However, treatment should always be preceded by specific testing for coagulation studies, as well as measurement of the platelet count.

Nonimmune Hydrops

Cristina Tarango, Russell E. Ware

Keywords

hydrops fetalis
mirror syndrome
nonimmune hydrops

Because of the success in preventing Rh alloimmune fetal hemolysis, nonimmune and often nonhematologic hydrops fetalis is the most common cause of fetal hydrops. **Hydrops** is defined by ≥2 abnormal fetal fluid collections, such as ascites, pleural, pericardial, or cutaneous edema (>5 mm) (Fig. 124.8). In addition, there may be associated placental edema (>6 mm), polyhydramnios (50%), and the rare occurrence of the **mirror syndrome** , in which the mother becomes edematous.

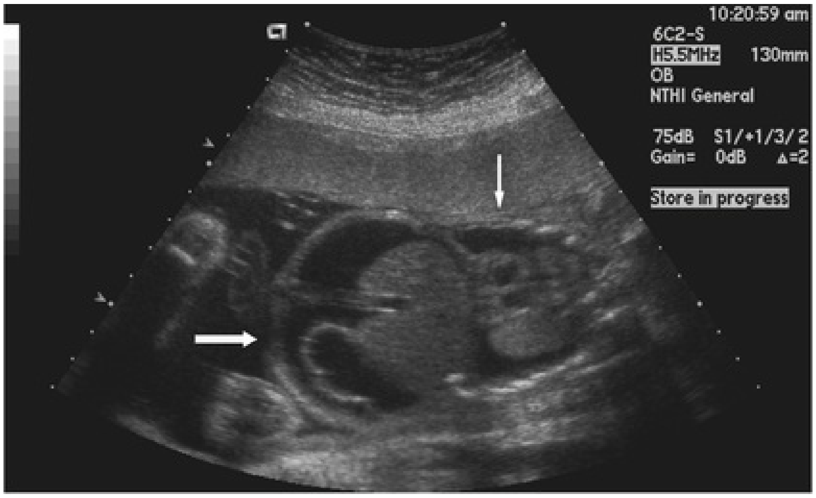

FIG. 124.8 **Hydrops fetalis. Longitudinal sonographic image of the fetus, with ascitic fluid outlining the liver *(large arrow).* The *small arrow* shows pleural effusion above the diaphragm. (From Wilkins I: Nonimmune hydrops. In Creasy RK, Resnick R, Iams JD, et al, editors: *Creasy & Resnik's maternal-fetal medicine,* ed 7, Philadelphia, 2014, Elsevier, Fig 37-2.)**

The incidence of nonimmune hydrops is approximately 1 in 3,000 births, many of whom are premature. The etiologies are broad; cardiac (structural and SVT) and chromosome disorders are the most common identifiable etiologies (Table 124.7). The etiology is unknown in 10–20%. The mechanisms for the development of nonimmune hydrops are not well established (Fig. 124.9).

In utero treatment has been successful for fetal supraventricular tachycardia (SVT), twin-twin transfusion syndrome, nonimmune fetal anemias, and some surgically treatable fetal conditions. Postnatal therapy includes a team approach to the delivery room management that often requires immediate endotracheal tube intubation and packed RBC transfusion in the presence of anemias. In premature infants, endotracheal surfactant is indicated; drainage of large pleural or pericardial effusions may also be needed. Once the infant is stabilized, diagnostic testing will direct further therapy based on the etiology. For patients with no obvious etiology, lymphangiography, whole exome (or genome) sequencing, and microarray duplication/deletion studies are recommended to establish a diagnosis.

Mortality is approximately 50% and is highest in the most premature infants, those with aneuploidy, and those with fetal anasarca.

CHAPTER 125

The Umbilicus

Amy T. Nathan

Umbilical Cord

The umbilical cord typically consists of 2 umbilical arteries, the umbilical vein, and a gelatinous substance called Wharton's jelly, all contained within a sheath derived from the amnion and coiled into a helical shape. The muscular umbilical arteries carry deoxygenated blood from the fetus to the placenta and are contiguous with the fetal internal iliac arteries. The umbilical vein carries oxygenated blood from the placenta back to the fetus, where it flows into the inferior vena cava by way of the ductus venosus. The umbilical cord itself contains an estimated 20 mL/kg of blood, and current recommendations are to delay clamping of the cord at delivery for 30-60 sec, to facilitate placental transfusion. At term, a normal umbilical cord is approximately 55 cm long. Abnormally short cords are associated with conditions causing decreased fetal movement, including fetal hypotonia, oligohydramnios, and uterine constraint, and lead to increased risk for complications during labor and delivery for both mother and infant. Long cords (>70 cm) increase the risk for true knots, wrapping around the fetus, and/or prolapse. Straight uncoiled cords are associated with anomalies, fetal distress, and intrauterine fetal demise.

When the cord is cut after birth, portions of these structures remain in the base but gradually become obliterated. The blood vessels are functionally closed but anatomically patent for 10-20 days. The umbilical arteries become the lateral umbilical ligaments; the umbilical vein, the ligamentum teres; and the ductus venosus, the ligamentum venosum. The umbilical cord stump usually sloughs within 2 wk. Delayed separation of the cord, after more than 1 mo, has been associated with neutrophil chemotactic defects and overwhelming bacterial infection (see Chapter 153).

A single umbilical artery is present in approximately 5-10/1,000 births; the frequency is higher (35-70/1,000) in twin births. It is estimated that 30% of infants with a single umbilical artery have other (and often multiple) congenital structural abnormalities. The presence of multiple anomalies is suggestive of an abnormal karyotype, including trisomies. Infants with isolated single umbilical artery are not thought to be at increased risk of having a chromosomal anomaly, and no specific evaluation is indicated for these infants aside from a thorough physical examination.

The **omphalomesenteric duct (OMD)** is an embryonic connection between the developing midgut and the primitive yolk sac. It typically involutes at 8-9 wk gestation, but failure of this process can leave an abnormal connection between the umbilical cord and the gastrointestinal (GI) tract. The most common remnant of the OMD is a **Meckel diverticulum** (see Chapter 357), whereas abnormalities that would become symptomatic in the neonatal period include a **sinus** or **fistula** that would drain mucus or intestinal contents through the umbilicus. An umbilical **polyp** is one of the least common OMD remnants and represents exposed GI mucosa at the umbilical stump. The tissue of the polyp is bright red, firm, and has a mucoid secretion. Therapy for all OMD remnants is surgical excision of the anomaly.

A **persistent urachus** (urachal cyst, sinus, patent urachus, or diverticulum) is a result of failure of closure of the allantoic duct and may be associated with bladder outlet obstruction. Patency should be suspected if a clear, light-yellow, urine-like fluid is being discharged from the umbilicus. Symptoms include drainage, a mass or cyst, abdominal pain, local erythema, and infection. Urachal anomalies should be investigated by ultrasonography and a cystogram. Therapy for a persistent urachus is surgical excision of the anomaly and correction of any bladder outlet obstruction if present.

Hemorrhage

Hemorrhage from the umbilical cord may be the result of trauma, inadequate ligation of the cord, or failure of normal thrombus formation. It may also indicate hemorrhagic disease of the newborn or other coagulopathies (especially factor XIII deficiency), septicemia, or local infection. The infant should be observed frequently during the first few days of life so that if hemorrhage does occur, it will be detected promptly.

Granuloma

The umbilical cord stump usually dries and separates within 1-2 wk after birth. The raw surface becomes covered by a thin layer of skin; scar tissue forms, and the wound is usually healed within 12-15 days. The presence of saprophytic organisms delays separation of the cord and increases the possibility of invasion by pathogenic organisms. Mild infection or incomplete epithelialization may result in a moist, granulating area at the base of the cord with a slight mucoid or mucopurulent discharge. Good results are usually obtained by cleansing with alcohol several times daily.

Persistence of granulation tissue at the base of the umbilicus is common. The tissue is soft, 3-10 mm in size, vascular and granular, colored dull red or pink, and may have a seropurulent discharge. Granulation tissue is treated by cauterization with silver nitrate, repeated at intervals of several days until the base is dry.

Infections

The devitalized umbilical cord provides an ideal medium for bacterial growth and a potential portal of entry for microbes. The term **omphalitis** refers to infection of the umbilical cord stump, navel, or the surrounding abdominal wall. The presence of cellulitis is associated with a high incidence of bacteremia, and complicated omphalitis may spread to the peritoneum, the umbilical or portal vessels, or the liver. **Necrotizing fasciitis** (which is often polymicrobial) is associated with a high mortality rate. Treatment of omphalitis includes prompt antibiotic therapy with agents effective against *Staphylococcus aureus* and *Escherichia coli* , such as an antistaphylococcal penicillin or vancomycin in combination with an aminoglycoside. If abscess formation has occurred, surgical incision and drainage may be required.

In community and primary care settings in developing countries, topical application of chlorhexidine to the umbilical cord has been shown to reduce omphalitis and neonatal mortality. However, the ideal approach to postnatal cord care in hospital settings in developed countries is still debated. There is no convincing evidence that application of antiseptics (including triple dye, alcohol, or chlorhexidine) is superior to dry cord care in minimizing the risk of omphalitis for infants in these settings, although these treatments do reduce bacterial colonization. The American Academy of Pediatrics does not currently recommend any particular method of cord care as superior in the prevention of infection.

Umbilical Hernia

Often associated with **diastasis recti** , an umbilical hernia is caused by incomplete closure or weakness of the muscular umbilical ring. Predisposing factors include black race and low birthweight. The hernia appears as a soft swelling covered by skin that protrudes during crying, coughing, or straining and can be reduced easily through the fibrous ring at the umbilicus. The hernia consists of omentum or portions of the small intestine. The size of the defect varies from <1 cm in diameter to as much as 5 cm (2 inches), but large defects are rare. Most umbilical hernias that appear before age 6 mo disappear spontaneously by 1 yr. Even large hernias (5-6 cm in all dimensions) have been known to disappear spontaneously by 5-6 yr. **Strangulation** of intestinal contents is extremely rare. Surgery is not advised unless the hernia persists to age 4-5 yr, causes symptoms, becomes strangulated, or becomes progressively larger after age 1-2 yr. Defects exceeding 2 cm are less likely to close spontaneously.

Congenital Omphalocele

An **omphalocele** is a herniation or protrusion of the abdominal contents into the base of the umbilical cord (Fig. 125.1). In contrast to the more common umbilical hernia, the sac is covered with peritoneum without overlying skin, and the insertion of the distal umbilical cord into the sac itself distinguishes this condition from other abdominal wall defects such as gastroschisis. The size of the sac that lies outside the abdominal cavity depends on its contents. **Herniation** of intestines into the cord occurs in approximately 1/5,000 births, and herniation of liver and intestines in 1/10,000 births. The abdominal cavity may be proportionately small because of the lack of space-occupying viscera. Treatment for an omphalocele consists of covering the sac with moist, sterile dressings, then initiating prompt surgical repair if the abdomen is able to accommodate the eviscerated organs. If the omphalocele is too large to allow immediate repair, continued dressings may temporize and encourage epithelialization of the sac. Occasionally, mesh or similar synthetic material may be used to cover the viscera if the sac has ruptured or if excessive mobilization of the tissues would be necessary to cover the mass and its intact sac.

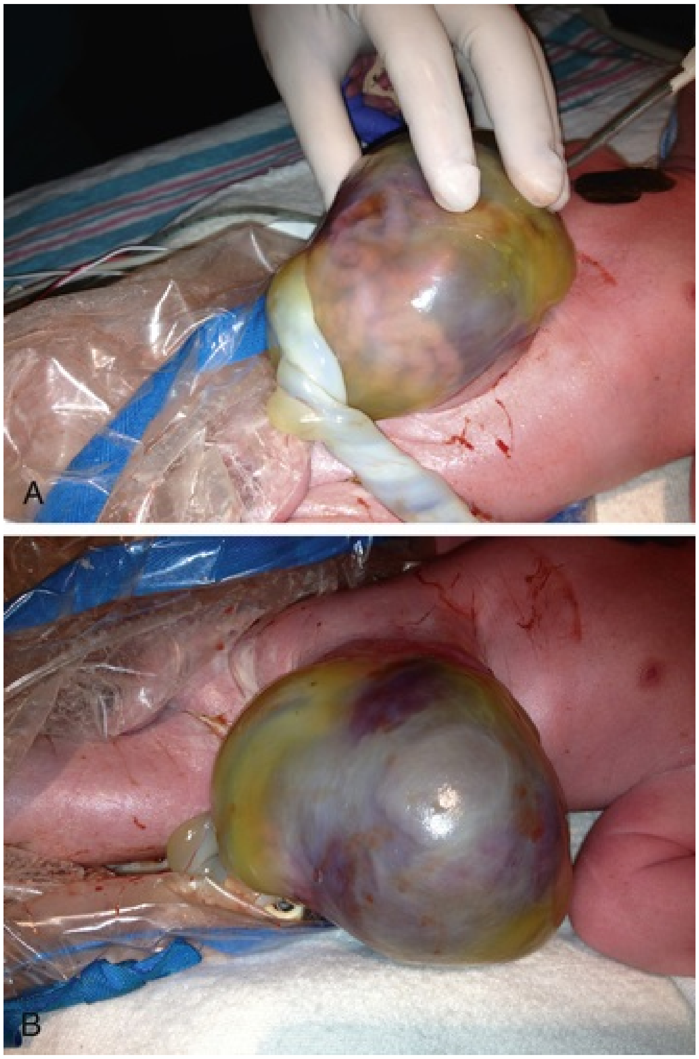

FIG. 125.1 **A,** Omphalocele with umbilical cord insertion into the sac and intestine visible. **B,** Omphalocele with sac containing liver. (Courtesy of Dr. Foong Lim, Cincinnati Fetal Center at Cincinnati Children's Hospital Medical Center.)

Many infants with omphalocele (50–70%) have associated malformations, and about 30% have chromosomal abnormalities. The likelihood of an abnormal karyotype is increased when the liver is *intracorporeal* (not within the sac). Omphalocele can be part of well-defined syndromes, including **Beckwith-Wiedemann syndrome** , characterized by omphalocele, macrosomia, and hypoglycemia. The survival rate for affected infants is largely determined by the presence of associated malformations or chromosomal abnormalities. For patients with isolated omphalocele, the survival rate is >90%.

Tumors

Tumors of the umbilicus are rare and include angioma, enteroteratoma, dermoid cyst, myxosarcoma, and cysts of urachal or OMD remnants.

CHAPTER 126

Abstinence Syndromes

126.1

Neonatal Abstinence (Withdrawal)

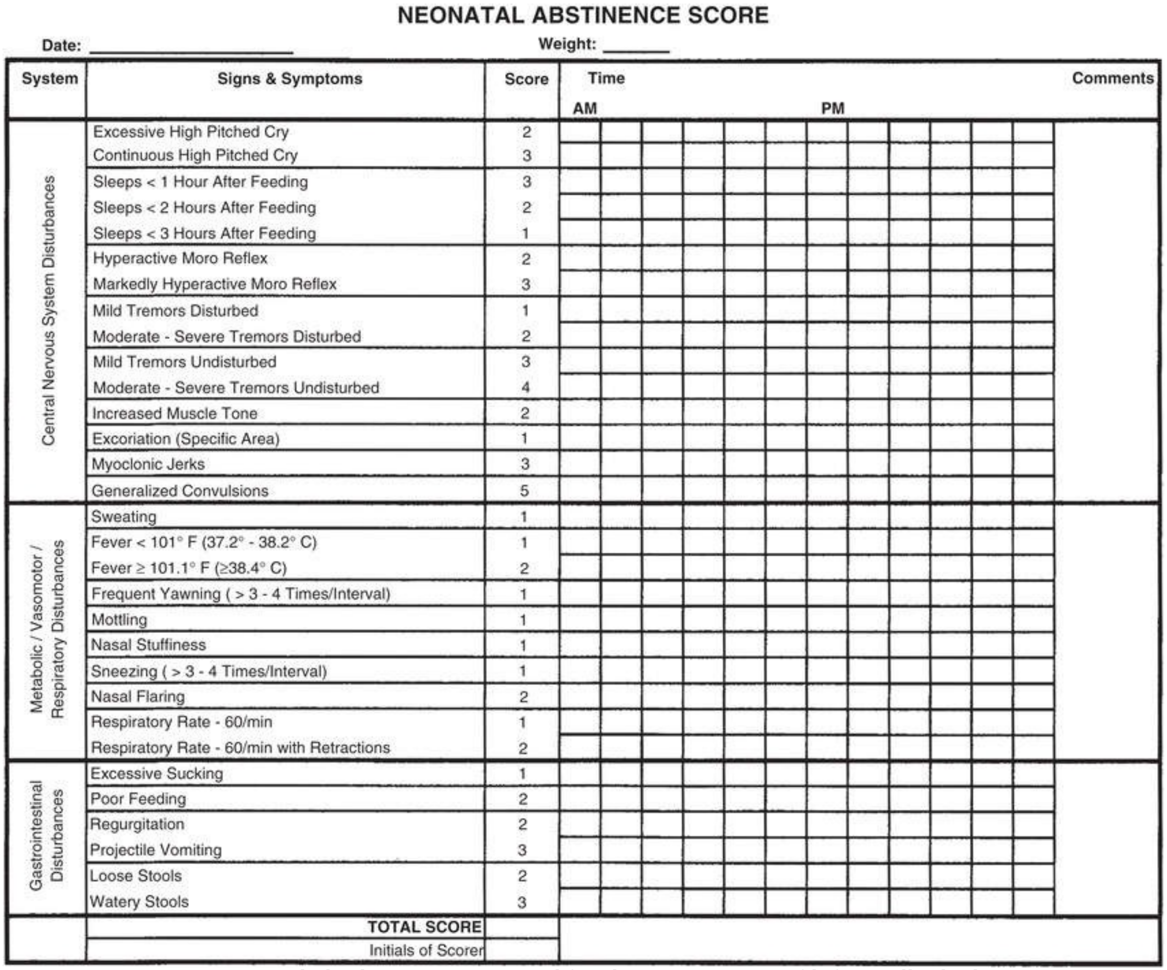
Scott L. Wexelblatt

Keywords

- benzodiazepine
- buprenorphine
- cocaine
- MAT
- medication-assisted treatment
- methadone
- methamphetamine
- NAS
- neonatal abstinence syndrome
- opioid
- phenobarbital

Neonatal abstinence syndrome (NAS) is the clinical diagnosis given to infants who experience withdrawal signs after in utero exposure to opioids. Withdrawal signs develop in 55–94% of opioid-exposed infants, 30–65% of whom need pharmacologic treatment for severe withdrawal. The incidence of NAS has been increasing yearly since 2004 and was 5 times more prevalent in 2013 than 2004. This increase in NAS is caused by increased use of prescription medication by pregnant women, an increase in **medication-assisted treatment (MAT)** for opioid addiction, an increase in illicit use of prescription medications, and increased use of heroin. In 2011, 1.1% of pregnant women in the United States abused pain relievers and heroin, and up to 12.9–28% of women were prescribed an opioid at some point during their pregnancy. Many factors affect the severity and duration of withdrawal, including tobacco use during pregnancy, breastfeeding after delivery, rooming-in and parental involvement, genetic makeup, and polysubstance use.

The clinical signs of NAS result from central nervous system (CNS) hyperexcitability and autonomic instability (Fig. 126.1). NAS signs can begin within 24 hr of birth after heroin exposure, within 48 hr after short-acting opioids, and 72-96 hr after exposure to long-acting opioids such as methadone and buprenorphine. Tremors, poor feeding, excessive crying, poor sleeping, and hyperirritability are the most prominent signs of NAS. Other signs include sneezing, yawning, hiccups, myoclonic jerks, skin breakdown and abrasions, vomiting, loose stools, nasal stuffiness, and seizures in the most severe cases.



NEONATAL ABSTINENCE SCORE

Date: ____________________ Weight: _______

System	Signs & Symptoms	Score	Time												Comments
			AM						PM						
Central Nervous System Disturbances	Excessive High Pitched Cry	2													
	Continuous High Pitched Cry	3													
	Sleeps < 1 Hour After Feeding	3													
	Sleeps < 2 Hours After Feeding	2													
	Sleeps < 3 Hours After Feeding	1													
	Hyperactive Moro Reflex	2													
	Markedly Hyperactive Moro Reflex	3													
	Mild Tremors Disturbed	1													
	Moderate - Severe Tremors Disturbed	2													
	Mild Tremors Undisturbed	3

	Projectile Vomiting	3													
	Loose Stools	2													
	Watery Stools	3													
	TOTAL SCORE														
	Initials of Scorer														

FIG. 126.1 Neonatal abstinence score used for the assessment of infants displaying neonatal abstinence syndrome. Evaluator should check sign or symptom observed at various time intervals. Add scores for total at each evaluation. (Adapted from Finnegan LP, Kaltenbach K. The assessment and management of neonatal abstinence syndrome. In Hoekelman RA et al, editors: *Primary pediatric care,* ed 3, St Louis, 1992, Mosby, p 1367.)

Identifying which infants are at risk for NAS before discharge is important because of the late onset of signs. Universal maternal screening for drug use is recommended by the American College of Obstetricians and Gynecologists (ACOG), and maternal consent should be obtained if drug testing is indicated. Universal maternal drug testing has been shown to improve identification of infants at risk for NAS but is more expensive and may not be helpful in states with punitive legislation. Maternal testing is preferred over infant testing because results are available promptly, typically by the time the infant is delivered. Testing mothers on admission to the hospital can also exclude iatrogenic exposure. Infant urine, meconium and umbilical cord testing are also used to help identify infants at risk for withdrawal and identify more distant use by the mother. Timing of these results and special collection methods makes routine use of these tests more difficult. Detectability in the neonatal urine specimen is typically 2-3 days for methadone (up to 6 days for methadone metabolites) and buprenorphine and 1-2 days for heroin.

MAT has been shown to be useful for pregnant women with an opioid substance use disorder. Mothers receiving MAT have a decreased mortality, reduced illicit drug use, reduced seroconversion of HIV, and decreased criminal activity. The most common medications in MAT are methadone or buprenorphine. Methadone is a full μ-opioid agonist with a half-life of 24-36 hr, given once daily in methadone clinics because of the potential for overdose. Buprenorphine is a partial μ-opioid agonist with a half-life of 36-48 hr, prescribed monthly as home therapy because a ceiling effect protects against overdosages.

Treatment

The first line of treatment for all opioid-exposed infants is **nonpharmacologic support** , which includes swaddling, placing the infant in a dark and quiet environment (e.g., dimmed lights, muted televisions), holding and Kangaroo care, reducing stimulation, and breastfeeding. Illicit (if continued) drug use is a contraindication to breastfeeding infants with NAS. Maternal methadone or buprenorphine use and hepatitis C are not contraindications to breastfeeding. Standardization of nonpharmacologic care with increased emphasis on clinical assessment(i.e., is the infant feeding well, sleeping well, and easily consoled?) over formal scoring tools, which typically require disturbing the infant, was associated with significantly less opioid use among infants with in utero methadone exposure.

The decision for pharmacologic treatment has been traditionally based on the nursing scoring assessment tool. The most widely used tools are the Finnegan and Modified Finnegan (Fig. 126.1). Other scoring tools include the Lipsitz, Neonatal Narcotic Withdrawal Index, Neonatal Withdrawal Inventory, and MOTHER NAS Scale. The main objectives when initiating pharmacologic treatment are to improve signs and comfort of the infant and to prevent worsening withdrawal that could lead to seizures.

Pharmacologic treatment for NAS, when necessary, is typically morphine or methadone (Table 126.1). **Morphine** is a short-acting opioid given every 3-4 hr as a weight-based or symptom-based regimen. **Methadone** is long-acting opioid that can be given twice a day after loading doses, and a pharmacokinetic weight-based weaning protocol is available. Sublingual **buprenorphine** has been proposed as an alternate treatment. Buprenorphine and some methadone formulations contain high ethanol levels, which may be deleterious to the infant. Following a stringent NAS protocol with guidelines on initiation and weaning has been shown to decrease both length of stay and number of opioid treatment days and may be as important as which primary opioid is used for first-line treatment.

Table 126.1

Medications Used in Pharmacologic Treatment of Neonatal Abstinence Syndrome (NAS)

DRUG	INITIAL DOSING	DOSING INCREASES	WEANING SCHEDULE	ADD ADJUVANT THERAPY
Morphine	0.05 mg/kg/dose q3h	Increase dose 10–20%	10% of stabilizing dose q24h	>1 mg/kg/day of morphine Unable to wean for 2 days
Methadone	0.1 mg/kg/dose q6h for 4 doses	Increase to q4h if unable to capture	0.7 mg/kg/dose q12h × 2 doses, then 0.05 mg/kg/dose q12h × 2; 0.04 mg/kg/dose q12h × 2; 0.03 mg/kg/dose q12h × 2; 0.02 mg/kg/dose q12h × 2; 0.01 mg/kg/dose q12h × 2; 0.01 mg/kg/dose q24h × 1	Unable to wean for 2 days
Buprenorphine	4 µg/kg q8h	2 µg/kg until maximum of 15 µg/kg	3 µg/kg/dose q8h × 3 doses; 2 µg/kg/dose q8h × 3; 2 µg/kg/dose q8h × 2; 2 µg/kg/dose q24h × 1	Unable to wean for 2 days
Phenobarbital	20 mg/kg	—	5 mg/kg daily	N/A
Clonidine	1.5 µg/kg/dose q3h	25% dose escalation q24hr	10% every day	N/A

N/A, Not available; q24h, every 24 hours.

Adjuvant therapy is initiated when the primary opioid is not effective in controlling the signs of NAS. The 2 most common medications used as adjuvant therapy are **phenobarbital** and **clonidine** . Infants with NAS may also expend additional energy. Therefore, the infant should be weighted regularly and strategies to increase caloric intake implemented if weight loss beyond that expected in the 1st week of life occurs.

The long-term prognosis for infants with NAS is multifactorial and not fully known. Close follow-up needs to be initiated to monitor growth and development, visual disturbances, and behavioral/learning problems.

Phenobarbital and benzodiazepine withdrawal may occur in infants of mothers addicted to these drugs, but signs are self-limiting and do not require pharmacologic treatment. Signs may be late onset and begin at a median age of 7 days (range: 2-14 days). Infants may have a brief acute stage consisting of irritability, constant crying, sleeplessness, hiccups, and mouthing movements, followed by a prolonged stage consisting of increased appetite, frequent spit-ups and gagging, irritability, sweating, and a disturbed sleep pattern, all of which may last for weeks.

Cocaine and methamphetamine abuse in pregnant women is less common than opioid abuse, and acute withdrawal in these infants is unusual. However, labor complications can be severe with both drugs and may include preterm labor, placental abruption, intrauterine growth restriction, and fetal asphyxia. Detection in neonatal urine is 6-8 hr for cocaine and 1-2 days for methamphetamine. Early on, exposed infants may have abnormal sleep patterns, poor feeding, tremors, and hypertonia. Long-term outcomes include impaired auditory information processing, developmental delay, and learning disabilities. At age 4 yr, children exposed prenatally to cocaine demonstrate cognitive impairments and are less likely to have an IQ above the normative mean.

126.2

Maternal Selective Serotonin Reuptake Inhibitors and Neonatal Behavioral Syndromes

---

Jennifer McAllister

Keywords

persistent pulmonary hypertension
PPHN
poor neonatal adaptation syndrome
PNAS
selective norepinephrine reuptake inhibitor
SNRI
selective serotonin reuptake inhibitor
SSRI
TCA
tricyclic antidepressant

Approximately 18% of women have depression during pregnancy. When pharmacologic treatment is required, selective serotonin reuptake inhibitors (SSRIs; fluoxetine, paroxetine, sertraline, citalopram, fluvoxamine) are most frequently prescribed. Additionally, serotonin norepinephrine reuptake inhibitors (SNRIs; venlafaxine, duloxetine) and tricyclic antidepressants (TCAs) have been used to treat pregnant women with depression or anxiety disorders. About 3.5% of all pregnant women in the Western world use psychotropic medications during their pregnancy, and all these agents cross the placenta. Exposure to these medications in utero may lead to a higher risk of congenital malformations, **poor neonatal adaptation syndrome** (PNAS), and **persistent pulmonary**

hypertension (PPHN).

Studies are conflicted on the risk of major birth defects, specifically cardiac defects, and antidepressant use in pregnancy. Use of paroxetine and fluoxetine are thought to have the highest risk of birth defects. Some reported defects include anencephaly, atrial septal defect, right ventricular outflow tract obstruction, omphalocele, and gastroschisis. Although the relative risk may be increased, the occurrence of birth defects is low.

PNAS symptoms usually appear within the 1st 8 hr after birth and often persist for the 1st 2-6 days of life. If symptoms do not develop within 48 hr, the infant is not likely to experience PNAS. PNAS affects the neurologic, autonomic, respiratory, and gastrointestinal systems. Symptoms include a weak suck reflex, irritability, tremors, hypertonia and hypotonia, hyperthermia, weak or absent cry, sleep disturbances, hypoglycemia, respiratory problems, vomiting and diarrhea, and seizures. Most symptoms are mild, and severe symptoms are rare. No deaths have been reported. Many researchers believe that the etiology of PNAS results from both toxicity and withdrawal from the antidepressant medications, and the symptoms of both toxicity and withdrawal are similar. Symptoms related to toxicity often occur *immediately after birth* when medication levels in the infant are high, whereas symptoms related to withdrawal often occur *8-48 hr after birth* when drug concentrations in the infants are low.

Most studies have reported incidence of PNAS with SSRI exposure to be approximately 30%. Exposure to SNRIs has a similar risk as SSRIs. Infants exposed to TCAs have a 20–50% risk of PNAS.

PPHN is often observed immediately after delivery, but symptoms can be variable in intensity, from mild respiratory insufficiency to severe respiratory failure. SSRI exposure later in pregnancy has been associated with a higher risk of PPHN.

Treatment consists of supportive measures, and most cases are mild, of short duration, and self-limiting. Small, frequent, on-demand feedings; swaddling; and skin-to-skin contact are beneficial to support infants through this process. Breastfeeding is protective against developing PNAS and should be encouraged because many antidepressant medications are safe with breastfeeding. Infants can be observed on the maternity ward with their mothers unless specific symptoms warrant further evaluation and treatment. Infants should be observed for a minimum of 48 hr to ensure they do not develop significant symptoms of PNAS. There have been no reported differences in IQ or development in infants with PNAS. Further research is needed to examine long-term effects of in utero antidepressant exposure.

126.3

Fetal Alcohol Exposure

Carol Weitzman

Keywords

fetal alcohol spectrum disorder
FASD
prenatal alcohol exposure
PAE

Epidemiology

Approximately 1 in 10 pregnant women report consuming alcohol within the past 30 days, and 1 in 33 report binge drinking. When pregnant women report binge drinking, they report an average of 4.6 binge-drinking episodes. Of nonpregnant women of childbearing age, approximately 50% report consuming alcohol within the last 30 days, with about 1 in 5 reporting binge drinking. Because almost 50% of pregnancies in the United States are unplanned, unintentional **prenatal alcohol exposure (PAE)** can occur before a woman knows she is pregnant.

Alcohol is a known teratogen that can cause irreversible CNS damage leading to CNS dysfunction that can range from relatively mild to severe. PAE affects all stages of brain development from neurogenesis to myelination, through mechanisms that include disrupted cell-cell interactions, altered gene expression, and oxidative stress leading to abnormalities such as reduced brain volume in the frontal lobe, striatum and caudate nucleus, thalamus, and cerebellum; thinning of the corpus callosum; and abnormal functioning of the amygdala.

Fetal alcohol spectrum disorders (FASDs) are the most common causes of preventable developmental delay and intellectual disability. Prevalence rates vary for several reasons. First, the method of ascertainment and the specific diagnostic definitions used can influence rates. Further, it is often difficult to obtain accurate information regarding PAE because mothers often deny the extent of alcohol use due to fear of child protective services and removal of their child from the home, shame and guilt associated with alcohol use during pregnancy, and fear of judgment. Lastly, mothers are often not asked in enough detail during or after pregnancy about alcohol consumption during pregnancy to accurately assess the extent of PAE. The U.S. Centers for Disease Control and Prevention (CDC) Fetal Alcohol Syndrome (FAS) Surveillance Network used medical records in several states and identified 0.3 children with FAS per 1,000 children age 7-9 yr. This prevalence rate is much lower than that obtained by active case ascertainment studies in the United States and Western Europe, which have estimated prevalence rates of 2–5%. Another study reported similar rates, 24-48 cases per 1,000 children (2.4–4.8%) for all FASDs, and 6-9 cases per 1,000 (0.6–0.9%) for FAS specifically. Studies that have examined PAE by anonymous meconium testing demonstrate 4.26 times greater identification of alcohol use during pregnancy compared with maternal self-report. Rates of FASDs have been reported to be higher in children living in poverty, in American Indian populations, and in children living in foster care. They often go undetected in these children, and as many as 86.5% of foster and adopted youth with FASDs go undiagnosed or are diagnosed incorrectly within the FAS spectrum.

Diagnostic Criteria

Updated clinical guidelines for diagnosing FASDs in the United States were published in 2016, as were updated Canadian guidelines, which overlap U.S. guidelines but also have important distinctions. PAE can result in a child having 1 of the FASDs, a nondiagnostic umbrella term in the United States. Diagnoses are determined based on the presence or absence of (1) the characteristic facial features; (2) prenatal/postnatal growth deficiency; (3) deficient brain growth, abnormal morphogenesis, or abnormal neurophysiology; (4) neurobehavioral impairment; and (5) maternal alcohol consumption during pregnancy.

FASDs include **fetal alcohol syndrome** (FAS), **partial fetal alcohol syndrome** (pFAS), **alcohol-related neurodevelopmental disorder** (ARND), **alcohol-related birth defect** (ARBD), and **neurobehavioral disorder associated with prenatal alcohol exposure** (ND-PAE), a term introduced in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5). Table 126.2 describes specific diagnostic features of each of the FASDs. The diagnosis of **FAS** and **pFAS** are the only FASDs that can be diagnosed in the absence of a confirmed maternal history of PAE. The key facial dysmorphologic features include short palpebral fissures, a thin vermilion border of the upper lip, and a smooth philtrum (Fig. 126.2). The differential diagnosis for FAS includes Williams syndrome, Dubowitz syndrome, fetal valproate syndrome, maternal phenylketonuria (PKU) effects, and other prenatal toxin exposures, and when there is unconfirmed PAE, a genetics evaluation may be warranted. **ND-PAE** is included in the DSM-5 as a “condition for further study” and is also provided as an example under “Other Specified Neurodevelopmental Disorder.” Although the diagnosis of ND-PAE overlaps with **ARND** , ND-PAE aims to describe the behavioral and mental health effects on an individual with PAE. Unlike ARND, a diagnosis of ND-PAE can be given in addition to FAS or pFAS. ND-PAE has organized the deficits seen into 3 areas: neurocognitive impairment, impaired self-regulation, and impairment in adaptive functioning. In the updated Canadian guidelines, “fetal alcohol spectrum disorder” is considered a diagnostic term with 2 categories: FASD with sentinel facial features and FASD without sentinel facial features. These guidelines have also eliminated *growth restriction* as a diagnostic criterion and have included an at-risk category for children with confirmed PAE who were too young to meet the criteria for neurodevelopmental deficits, or in whom assessment was incomplete, and for children with cardinal facial features without documentation or evidence of severe impairment in neurodevelopmental domains.

Table 126.2

Diagnostic Features of Fetal Alcohol Spectrum Disorders (FASDs)

TYPE OF FASD	FACIAL DYSMORPHOLOGY	GROWTH		DEFICIENT BRAIN GROWTH, ABNORMAL MORPHOGENESIS, OR ABNORMAL NEUROPHYSIOLOGY	NEUROBEHAVIOR FEATURES
Fetal alcohol syndrome (FAS)	≥2 of the following: Short palpebral fissures (≤10th centile) Thin vermilion border of upper lip Smooth philtrum	Height and/or weight ≤10th centile	*OR*	Head circumference ≤10th centile Structural brain anomalies Recurrent nonfebrile seizures	*With cognitive impairment:* Evidence of globa impairment (gene conceptual ability ≥1.5 SD below th mean *or* Cognitive deficit i at least 2

					neurobehavioral domains ≥1.5 SD below the mean *With behavioral impairment witho cognitive impairment:* Evidence of behavioral deficit at least 2 domains ≥1.5 SD below th mean
Partial FAS (pFAS)	≥2 of the following: Short palpebral fissures (≤10th centile) Thin vermilion border of upper lip Smooth philtrum	Height and/or weight ≤10th centile	*OR*	Head circumference ≤10th centile Structural brain anomalies Recurrent nonfebrile seizures	*With cognitive impairment:* Evidence of globa impairment (gene conceptual ability ≥1.5 SD below th mean *or* Cognitive deficit i at least 2 neurobehavioral domains ≥1.5 SD below the mean *With behavioral impairment witho cognitive impairment:* Evidence of behavioral deficit at least 2 domains ≥1.5 SD below th mean
Alcohol-related neurodevelopmental disorder (ARND)	—	—		—	*With cognitive impairment:* Evidence of globa impairment (gene conceptual ability ≥1.5 SD below th mean *or* Cognitive deficit i at least 2 neurobehavioral domains ≥1.5 SD below the mean *With behavioral impairment witho cognitive impairment:* Evidence of behavioral deficit at least 2 domains ≥1.5 SD below th mean

Alcohol-related birth defect (ARBD)	—	—		One or more specific major malformations demonstrated in animal models and human studies to be the result of prenatal alcohol exposure	—
Neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE)	—	—		—	**Neurocognitive impairment (1)** Global intellect Executive functioning Learning Memory Visual-spatial reasoning **Impaired self-regulation (1)** Mood or behavior Attention Impulse control **Impairments in adaptive functioning (2)** Language Social communication a interaction Daily living skills Motor skills

* Documented prenatal alcohol exposure:
- ≥6 drinks/wk for ≥2 wk during pregnancy.
- ≥3 drinks per occasion on ≥2 occasions during pregnancy.
- Documentation of alcohol-related social or legal problems in proximity to (before or during) the index pregnancy (e.g., driving while intoxicated or history of treatment of an alcohol-related condition).
- Documentation of intoxication during pregnancy by blood, breath, or urine alcohol content testing.
- Increased prenatal risk associated with drinking during pregnancy as assessed by a validated screening tool.

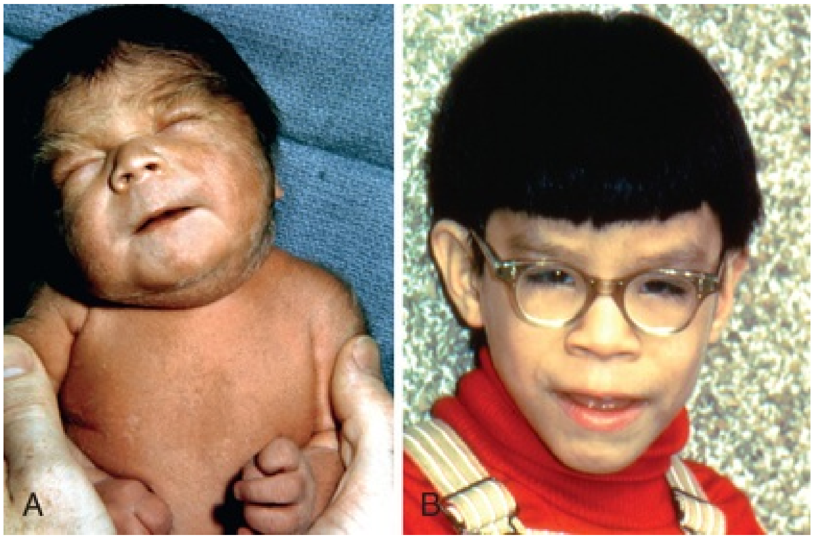

FIG. 126.2 **Characteristics of fetal alcohol syndrome. At birth (A) and at 4 yr of age (B). Note the short palpebral fissures; long, smooth philtrum with vermilion border; and hirsutism in the newborn. (From Jones KL, Smith DW: Recognition of the fetal alcohol syndrome in early infancy, *Lancet* 2:999–1001, 1973.)**

A safe threshold or pattern of alcohol consumption has not been identified, and any PAE is believed to present a risk to a developing fetus. Significant alcohol exposure has been carefully defined in the updated guidelines, and information can be obtained from a variety of sources, including, in addition to the birth mother, family members, foster or adoptive parents, social service agencies who observed maternal alcohol consumption during pregnancy, or medical records that document PAE, alcohol treatment, or social, legal, or medical problems related to drinking during pregnancy. PAE in the first trimester leads to the classic *facial dysmorphia* associated with FAS and other structural defects. PAE can have other deleterious effects (e.g., spontaneous abortion, growth defect) on the fetus throughout the pregnancy. Several well-validated screens are used to identify alcohol use in pregnant and nonpregnant women of childbearing years, including the T-ACE (Tolerance, Annoyance, Cut Down, Eye-Opener), CAGE (Cut Back, Annoyed, Guilty, Eye-Opener), CRAFFT, Audit-C (Alcohol Use Disorders Identification Test), and TWEAK (Tolerance, Worried, Eye opener, Amnesia, Kut Down). There are no well-validated screens designed to ask about past consumption of alcohol. Pediatricians can ask the following 2 questions to determine the likelihood of significant PAE: “In the 3 months before you knew you were pregnant, how many times did you have 4 or more alcohol drinks in a day?” and “During your pregnancy, how many times did you have any alcohol?” If a positive response is given to either question, the clinician can follow up to determine the level of PAE by asking, (1) “During your pregnancy, on average, how many days per week did you have any alcohol?” (2) “During your pregnancy, on a typical day when you had an alcoholic beverage, how many drinks did you have?” and (3) “During your pregnancy, what was the maximum number of drinks that you had in a day?”

Clinical Features

There is tremendous variability in the presentation of the neurobehavioral and neurocognitive features of children with FASD due to the timing and amount of PAE and unique characteristics of the birth mother and the child. Presentation can range from relatively mild developmental delays to severe intellectual disability, although approximately 75% of individuals with an FASD do not have intellectual disability. In infants, the symptoms can be nonspecific and may include irritability, poor feeding, sleep difficulties, a tendency to become easily overstimulated, or difficulty forming attachments with caregivers. Young children may demonstrate developmental delays, inattention, impulsivity, internalizing and externalizing problems, social impairments and difficulty with peers, and behavioral difficulties such as mood lability, frequent tantrums or aggression. The neurocognitive profile of children with an FASD that emerges in elementary or middle school includes challenges with processing speed, memory, visual-spatial reasoning, math, auditory comprehension, use of pragmatic language, and executive functioning skills. Learning strengths often include decoding, reading, and speech. In adolescents, difficulties with abstract reasoning, time and money management, and social and adaptive skills may become more pronounced.

The most common comorbid mental health condition seen in children with an FASD is attention-deficit/hyperactivity disorder (see Chapter 49), which occurs in >50% of children. Individuals with FASD may present with problems of self-regulation, impulse control, and adaptive functioning. Additional mental health disorders typically seen in children and adolescents with an FASD include oppositional defiant and conduct disorder, anxiety disorder, adjustment disorder, sleep disorder, mood disorders (e.g., depression, bipolar disorder), and disinhibited social engagement disorder. FASD may increase the severity or complexity of these conditions.

Interventions and Treatment

Given the heterogeneity of presenting problems associated with the FASDs, interventions need to be tailored to address each individual child or adolescent's profile of strengths and difficulties. Although the evidence base examining interventions for children and adolescents with an FASD is limited, with most studies having small sample sizes, there is emerging evidence for effective programs and treatments specifically designed for children with an FASD. Studies support that the most successful interventions begin early and continue across the life span, include a preventive focus, are intensive and individualized, address multiple domains of functioning, include parent education and training, and are coordinated across systems of care. Children with an FASD often need support and intervention in the areas of learning, executive functioning, adaptive skills, social skills and peer relations, and mental health. To enhance generalizability of skills and to ensure they are encoded into memory, children with an FASD require consistent and predictable interventions, simplified directions, repeated instructions, and reduced distractions. Many children are treated with psychotropic medications, with stimulants most frequently prescribed. Children with an FASD are often treated with a higher number of drugs and at higher doses, likely because of atypical or less favorable responses.

Outcomes

Children with an FASD are at higher risk for **victimization and bullying** , often due to poor social judgment. Children and adolescents who are not identified early and aggressively treated are significantly more likely to have secondary disabilities, including encounters with juvenile justice and incarceration, substance abuse problems, severe mental health problems, sexual promiscuity and other inappropriate sexual behaviors, high rates of school failure, dropout and under- or unemployment, and health problems. Children and adolescents with an FASD have a 95% lifetime likelihood of having a mental health diagnosis and are at higher risk for **suicide** . Although an FASD cannot be cured, the long-term negative effects of the brain damage caused by PAE can be reduced through aggressive, sustained intervention initiated early. The estimated lifetime cost of caring for a child with FAS is $1.4 million, with average medical expenditures 9 times higher than expenses for children without FAS. These numbers increase significantly when the costs of caring for all children with any FASD are included.

The Pediatrician's Role

Pediatricians play an important role in identifying children and adolescents with an FASD, by asking parents about PAE and counseling mothers to abstain from alcohol consumption if they are planning to have additional children. Pediatricians need to screen all mothers for PAE and reduce the stigma associated with asking. They need to consider an FASD in a child who presents with complex neurodevelopmental and neurobehavioral problems, structural abnormalities, growth deficits, and facial dysmorphology. It is important that pediatricians remember that despite the increased risk in certain groups, FASDs occur across all economic, racial, and ethnic groups. Pediatricians need to document findings related to PAE and establish a **medical home** for the child with an FASD that includes a network of professionals who can help and support the child and family. The American Academy of Pediatrics has developed an FASD toolkit (www.aap.org/fasd) to assist primary care providers in identifying children with an FASD and managing their challenges in an effort to reduce the lifelong adverse consequences.

CHAPTER 127

The Endocrine System

Nicole M. Sheanon, Louis J. Muglia

Endocrine emergencies in the newborn period are uncommon, but prompt identification and proper treatment are vital to reduce morbidity and mortality.

Pituitary dwarfism (growth hormone deficiency) is not usually apparent at birth, although male infants with **panhypopituitarism** may have neonatal hypoglycemia, hyperbilirubinemia, and micropenis. Conversely, **primordial dwarfism** manifests as in utero growth failure that continues postnatally, with length and weight suggestive of prematurity when born after a normal gestational period; otherwise, physical appearance is normal.

Congenital hypothyroidism is one of the most common preventable causes of developmental disability. Congenital screening followed by thyroid hormone replacement treatment started within 30 days after birth can normalize cognitive development in children with congenital hypothyroidism. Congenital hypothyroidism occurs in approximately 1/2,000 infants worldwide (see Chapter 581). Because most infants with congenital hypothyroidism are asymptomatic at birth, all states screen for it. Even though screening is standard in many countries, millions of infants born throughout the world are not screened for congenital hypothyroidism. Thyroid deficiency may also be apparent at birth in genetically determined cretinism and infants of mothers with hyperthyroidism during pregnancy treated with antithyroid medications (PTU). Infants with trisomy 21 have a higher incidence of congenital hypothyroidism and should be screened in the newborn period. Constipation, prolonged jaundice, goiter, lethargy, umbilical hernia, macroglossia, hypotonia with delayed reflexes, mottled skin, or cold extremities should suggest severe chronic hypothyroidism. **Levothyroxine** is the treatment of choice, with the goal of rapid normalization of thyroid-stimulating hormone (TSH, thyrotropin) and free thyroxine (T_4) to achieve the best outcome. Thyroid hormone treatment is aimed to maintain total thyroxine or free thyroxine in the upper half of the normal range during the 1st 3 yr after birth. Early diagnosis and treatment of congenital thyroid hormone deficiency improve intellectual outcome and are facilitated by screening of all newborn infants for this deficiency. Newborn screening, with early referral to a pediatric endocrinologist for abnormal results, has improved early diagnosis and treatment of congenital hypothyroidism and improved intellectual outcome.

Transient hypothyroxinemia of prematurity is most common in ill and very premature infants. These infants have low thyroxine levels but normal levels of serum thyrotropin and other tests of the pituitary-hypothalamic axis indicating that they are probably chemically euthyroid. Trials of thyroid hormone replacement have reported no difference in developmental outcomes or other morbidities. Current practice is to follow thyroxine until levels normalize. **Transient hyperthyroidism** may occur at birth in infants of mothers with established or cured hyperthyroidism (e.g., Graves disease with positive TSH receptor–stimulating antibodies). See Chapter 584 for details on diagnosis and treatment.

Transient hypoparathyroidism may manifest as tetany or seizure of the newborn due to hypocalcemia and is associated with low levels of parathyroid hormone and hyperphosphatemia. Testing for DiGeorge syndrome should be considered. (see Chapter 589).

Subcutaneous fat necrosis can cause **hypercalcemia** and can occur after a traumatic birth. On examination, firm purple nodules can be appreciated on the trunk or extremities. An infant with hypercalcemia presents with irritability, vomiting, increased tone, poor weight gain, and constipation. Other causes of hypercalcemia in the newborn period are iatrogenic (excess calcium or vitamin D), maternal hypoparathyroidism, Williams syndrome, parathyroid hyperplasia, and idiopathic.

The adrenal glands are subject to numerous disturbances, which may become apparent and require lifesaving treatment during the neonatal period. Acute **adrenal hemorrhage** and adrenal failure are uncommon in the neonatal period. Risk factors include vaginal delivery, macrosomia, and fetal acidemia. The clinical presentation is often mild, with spontaneous regression. In neonates with bilateral adrenal hemorrhage, an evaluation of cortisol production is required (high-dose ACTH stimulation test), and, if insufficient, treatment with glucocorticoids and mineralocorticoids is indicated. Differentiation of unilateral adrenal hemorrhage from neuroblastoma is important. All patients should have sonographic and clinical follow-up to ensure resolution.

Congenital adrenal hyperplasia (CAH) is suggested by vomiting, diarrhea, dehydration, hyperkalemia, hyponatremia, shock, ambiguous genitalia, or clitoral enlargement. Some infants have ambiguous genitalia and hypertension. In an infant with ambiguous genitalia, both pelvic and adrenal ultrasound can be performed to aid in diagnosis. An adrenal ultrasound showing bilateral, enlarged, coiled or cerebriform pattern is specific for CAH. Diagnosis is confirmed with an elevated 17-hydroxyprogesterone level for gestational age. Because the condition is genetically determined, newborn siblings of patients with the salt-losing variety of adrenocortical hyperplasia should be closely observed for manifestations of adrenal insufficiency. Newborn screening and early diagnosis and therapy for this disorder may prevent severe salt wasting and adverse outcomes. Congenitally hypoplastic adrenal glands may also give rise to adrenal insufficiency during the 1st few wk of life (*DAX1* mutation).

Disorders of sexual development can present in the newborn period with ambiguous or atypical genitalia, including bilateral cryptorchidism, hypospadias, micropenis, hypoplastic scrotum, or clitoromegaly. More than 20 genes have been associated with disorders of sexual development. The initial management should involve a multidisciplinary team (endocrinology, urology, genetics, and neonatology) and open communication with the family. Sex assignment and naming of the infant should be delayed until appropriate testing is completed. For more about disorders of sexual development, see Chapter 606 .

Female infants with webbing of the neck, lymphedema, hypoplasia of the nipples, cutis laxa, low hairline at the nape of the neck, low-set ears, high-arched palate, deformities of the nails, cubitus valgus, and other anomalies should be suspected of having **Turner syndrome** . Lymphedema of the hands or lower extremities can sometimes be the only indication. A karyotype can confirm diagnosis (see Chapter 604.1).

Transient neonatal diabetes mellitus (TNDM) is rare and typically presents on day 1 of life (see Chapter 607). It usually manifests as polyuria, dehydration, loss of weight, or acidosis in infants who are small for gestational age. The most common cause (70%) is a disruption of the imprinted locus at chromosome 6q24. A select group of patients with TNDM are at risk for recurrence of diabetes later in life.

127.1

Infants of Diabetic Mothers

Nicole M. Sheanon, Louis J. Muglia

Keywords

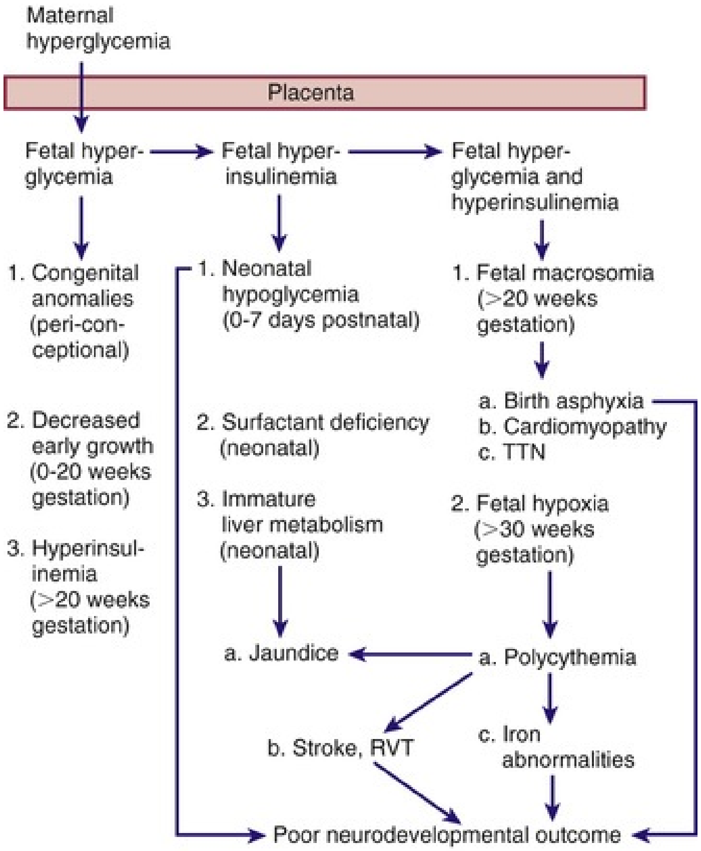
diabetic embryopathy
gestational diabetes
hyperglycemia
hyperinsulinemia
hyperinsulinism
hypoglycemia
IDMs
infants of diabetic mothers
pregestational diabetes

Diabetes (type 1, type 2, or gestational) in pregnancy increases the risk of complications and adverse outcomes in the mother and the baby. Complications related to diabetes are milder in gestational vs pregestational (preexisting type 1 or type 2) diabetes. Pregnancy outcomes are correlated with onset, duration, and severity of maternal hyperglycemia. Prepregnancy planning and tight glycemic control (hemoglobin A_{1c} [HbA_{1c}] <6.5%) is crucial in **pregestational diabetes** in order to achieve the best outcomes for the mother and the baby. The risk of **diabetic embryopathy** (neural tube defects, cardiac defects, caudal regression syndrome) and spontaneous abortions is highest in those with pregestational diabetes who have poor control (HbA_{1c} >7%) in the first trimester. The risk of congenital malformations in **gestational diabetes** is only slightly increased compared to the general population, since the duration of diabetes is less and hyperglycemia occurs later in gestation (typically >25 wk).

Mothers with pregestational and gestational diabetes have a high incidence of complications during the pregnancy. Polyhydramnios, preeclampsia, preterm labor (induced and spontaneous), and chronic hypertension occur more frequently in mothers with diabetes. Accelerated fetal growth is also common, and 36–45% of **infants of diabetic mothers (IDMs)** are born large for gestational age (LGA). Restricted fetal growth is seen in mothers with pregestational diabetes and vascular disease, but it is less common. Fetal mortality rate is greater in both pregestational and gestational diabetic mothers than in nondiabetic mothers, but the rates have dropped precipitously over the years. Fetal loss throughout pregnancy is associated with poorly controlled maternal diabetes, especially **diabetic ketoacidosis** . The neonatal mortality rate of IDMs is >5 times that of infants of nondiabetic mothers and is higher at all gestational ages and in every birthweight for gestational age category. The rate is higher in women with pregestational diabetes, smoking, obesity, hypertension, and poor prenatal care.

Pathophysiology

The probable pathogenic sequence is that maternal hyperglycemia causes fetal **hyperglycemia** , and the fetal pancreatic response leads to fetal **hyperinsulinemia** , or **hyperinsulinism** . It is important to recognize that while maternal glucose crosses the placenta, maternal and exogenous insulin dose not. Fetal hyperinsulinemia and hyperglycemia then cause increased hepatic glucose uptake and glycogen synthesis, accelerated lipogenesis, and augmented protein synthesis (Fig. 127.1). Related pathologic findings are hypertrophy and hyperplasia of the pancreatic β cells, increased weight of the placenta and infant organs (except the brain), myocardial hypertrophy, increased amount of cytoplasm in liver cells, and extramedullary hematopoiesis. Hyperinsulinism and hyperglycemia produce fetal acidosis, which may result in an increased rate of stillbirth. Separation of the placenta at birth suddenly interrupts glucose infusion into the neonate without a proportional effect on hyperinsulinism, leading to hypoglycemia during the 1st few hr after birth. The risk of rebound hypoglycemia can be diminished by tight blood glucose control during labor and delivery.



Maternal hyperglycemia
Placenta
Fetal hyper-glycemia
Fetal hyper-insulinemia
Fetal hyper-glycemia and hyperinsulinemia
1. Congenital anomalies (peri-con-ceptional)
2. Decreased early growth (0-20 weeks gestation)
3. Hyperinsul-inemia (>20 weeks gestation)
1. Neonatal hypoglycemia (0-7 days postnatal)
2. Surfactant deficiency (neonatal)
3. Immature liver metabolism (neonatal)
1. Fetal macrosomia (>20 weeks gestation)
a. Birth asphyxia
b. Cardiomyopathy
c. TTN
2. Fetal hypoxia (>30 weeks gestation)
a. Jaundice
a. Polycythemia
b. Stroke, RVT
c. Iron abnormalities
Poor neurodevelopmental outcome

FIG. 127.1 The fetal and neonatal events attributable to fetal hyperglycemia *(column 1),* fetal hyperinsulinemia *(column 2),* or both in synergy *(column 3).* Time of risk is denoted in parentheses. RVT, Renal vein thrombosis; TTN, transient tachypnea of the newborn. (From Nold JL, Georgieff MK: Infants of diabetic mothers, *Pediatr Clin North Am* 51:619–637, 2004.)

Hyperinsulinemia has been documented in infants of mothers with pregestational and gestational diabetes. The infants of mothers with *pregestational* diabetes have significantly higher fasting plasma insulin levels than normal newborns, despite similar glucose levels, and respond to glucose with an abnormally prompt elevation in plasma insulin. After arginine administration, they also have an enhanced insulin response and increased disappearance rates of glucose compared with normal infants. In contrast, fasting glucose production and utilization rates are diminished in infants of mothers with *gestational* diabetes. Although hyperinsulinism is probably the main cause of hypoglycemia, the diminished epinephrine and glucagon responses that occur may be contributing factors. Infants of mothers with pregestational and gestational diabetes are at risk for neonatal hypoglycemia in the 1st hours of life, with an increased risk in both large- and small-for-gestational-age infants. Aggressive screening and treatment is recommended as outlined later.

Clinical Manifestations

Infants of mothers with pregestational diabetes and those of mothers with gestational diabetes often bear a surprising resemblance to each other (Fig. 127.2). They tend to be large and plump as a result of increased body fat and enlarged viscera, with puffy, plethoric facies resembling that of patients who have been receiving corticosteroids. These infants may also be of normal birthweight if diabetes is well controlled; or low birthweight if they are delivered before term or if their mothers have associated diabetic vascular disease. Infants that are macrosomic or LGA are at high risk of birth trauma (brachial plexus injury) and birth asphyxia because of not only their large size but also their decreased ability to tolerate stress, especially if they have cardiomyopathy and other effects of fetal hyperinsulinemia (Table 127.1).

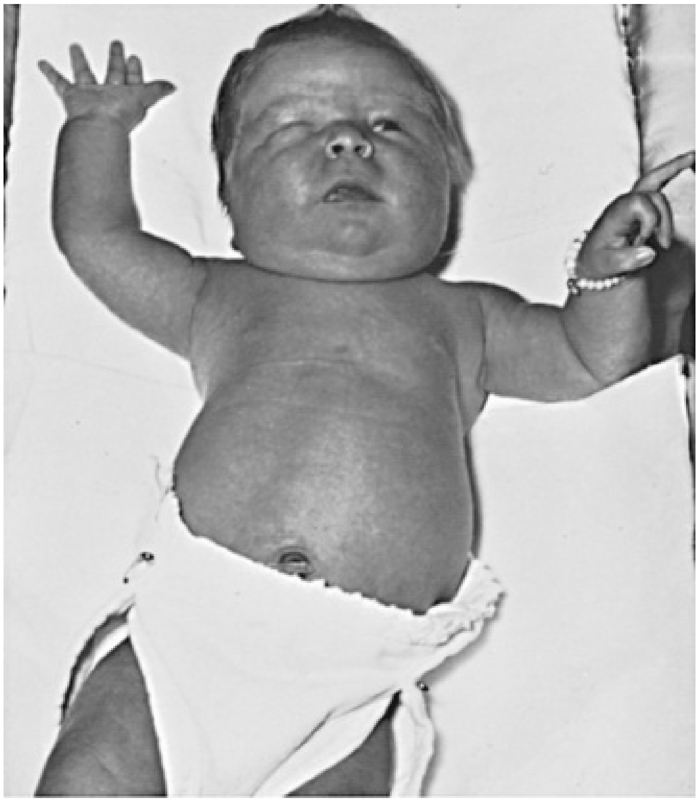


FIG. 127.2 **Large, plump, plethoric infant of a mother with gestational diabetes. The baby was born at 38 wk of gestation but weighed 9 lb, 11 oz (4,408 g). Mild respiratory distress was the only symptom other than appearance.**

Table 127.1

Morbidity in Infants of Diabetic Mothers

- Congenital anomalies
- Heart failure and septal hypertrophy of heart
- Surfactant deficiency, respiratory distress syndrome, transient tachypnea of the newborn, persistent pulmonary hypertension
- Hyperbilirubinemia
- Hypoglycemia, hypocalcemia, hypomagnesemia
- Macrosomia, nerve injury related to birth trauma
- Renal vein thrombosis
- Small left colon
- Unexplained intrauterine demise
- Polycythemia
- Visceromegaly
- Predisposition to later-life obesity, insulin resistance, and diabetes

From Devaskar SU, Garg M: Disorders of carbohydrate metabolism in the neonate. In Martin RJ, Fanaroff AA, Walsh MC, editors: *Fanaroff & Martin's neonatal-perinatal medicine,* ed 10, Philadelphia, 2015, Elsevier (Box 95-3).

Hypoglycemia develops in approximately 25–50% of infants of mothers with pregestational diabetes and 15–25% of infants of mothers with gestational diabetes, but only a small percentage of these infants become symptomatic. The probability that hypoglycemia will develop in such infants increases with higher cord or maternal fasting blood glucose levels. The nadir in an infant's blood glucose concentration is usually reached between 1 and 3 hr of age. Hypoglycemia can persist for 72 hr and in rare cases last up to 7 days. Frequent feedings can be used to treat the hypoglycemia, but some infants require intravenous (IV) dextrose.

The infants tend to be jittery, tremulous, and hyperexcitable during the 1st 3 days after birth, although hypotonia, lethargy, and poor sucking may also occur. Early appearance of these signs is more likely to be related to hypoglycemia but can also be caused by hypocalcemia and hypomagnesemia, which also occur in the 1st 24-72 hr of life due to delayed response of the parathormone system. Perinatal asphyxia is associated with increased irritability and also increases the risk of hypoglycemia, hypomagnesemia, and hypocalcemia.

Tachypnea develops in many IDMs during the 1st 2 days after birth and may be a manifestation of hypoglycemia, hypothermia, polycythemia, cardiac failure, transient tachypnea, or cerebral edema from birth trauma or asphyxia. IDMs have a higher incidence of **respiratory distress syndrome** (RDS) than do infants of nondiabetic mothers born at comparable gestational age. The greater incidence is possibly related to an antagonistic effect of insulin on stimulation of surfactant synthesis by cortisol, leading to a delay in lung maturation. Polycythemia often occurs with RDS as they are both a result of fetal hyperinsulinism.

Cardiomegaly is common (30%), and heart failure occurs in 5-10% of IDMs. Interventricular septal hypertrophy may occur and may manifest as transient idiopathic hypertrophic subaortic stenosis. This is thought to result from chronic hyperglycemia and chronic hyperinsulinism leading to glycogen loading in the heart. Inotropic agents worsen the obstruction and are contraindicated. β-Adrenergic blockers have been shown to relieve the obstruction, but ultimately the condition resolves spontaneously over time.

Acute neurologic abnormalities (lethargy, irritability, poor feeding) can be seen immediately after birth and the cause elucidated by the timing of symptoms, as previously discussed (hypoglycemia, hypocalcemia, hypomagnesemia, or birth asphyxia). The symptoms will resolve with treatment of the underlying cause but may persist for weeks if caused by birth asphyxia. Neurologic development and ossification centers tend to be immature and to correlate with brain size (which is not increased) and gestational age rather than total body weight in infants of mothers with gestational and pregestational diabetes. In addition, IDMs have an increased incidence of hyperbilirubinemia, polycythemia, iron deficiency, and renal vein thrombosis. Renal vein thrombosis should be suspected in the infant with a flank mass, hematuria, and thrombocytopenia.

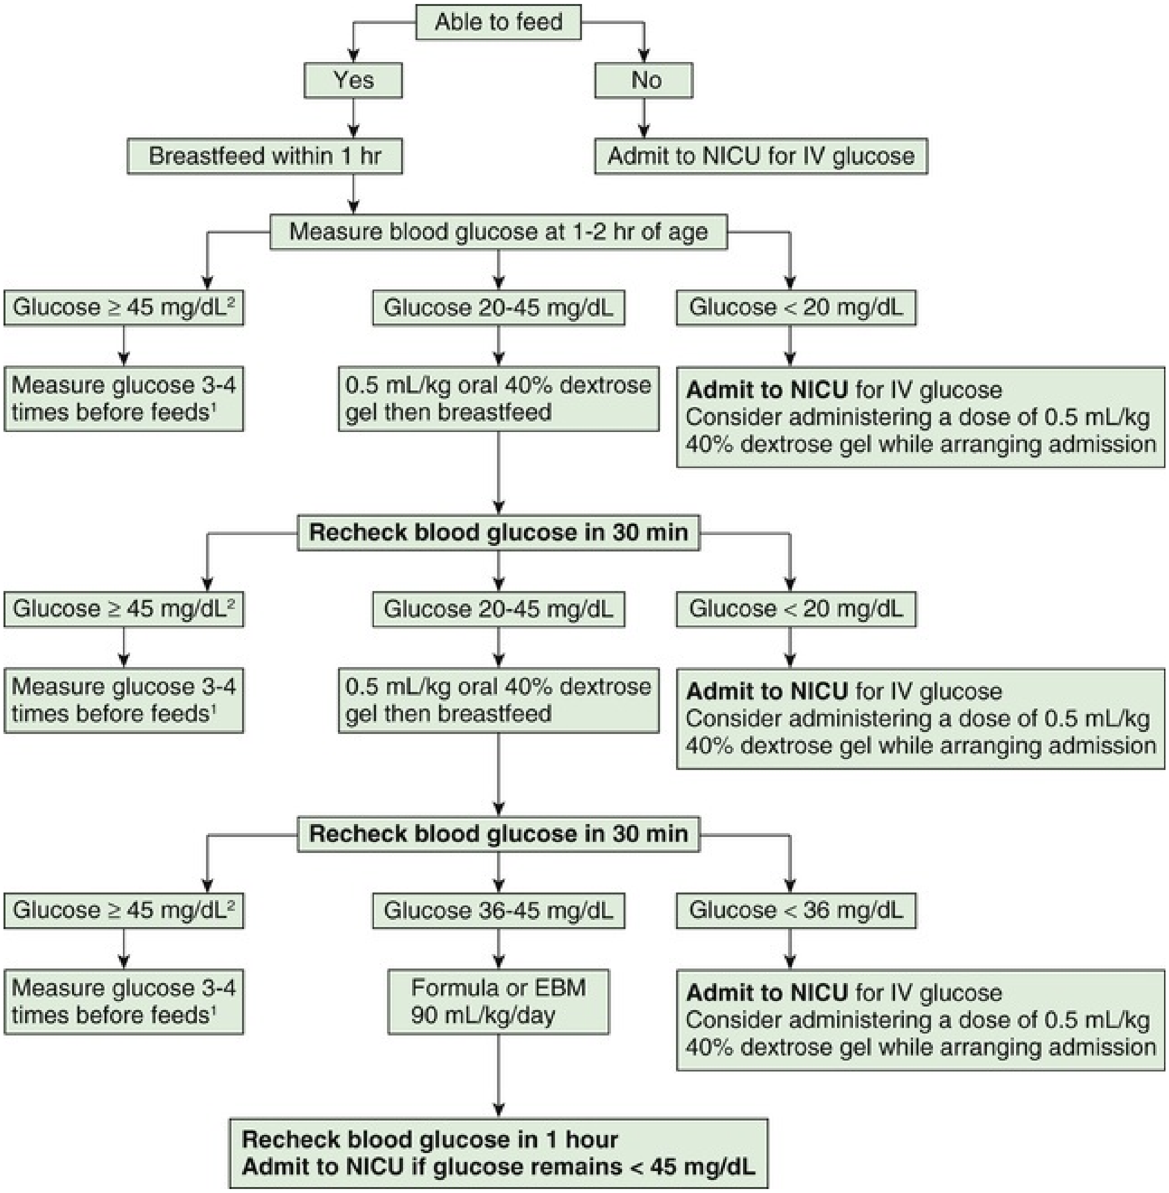
There is a 4-fold increase in **congenital anomalies** in infants of mothers with pregestational diabetes, and the risk varies with HbA_{1c} during the first trimester when organogenesis occurs. The recommended goal for periconceptual HbA_{1c} is <6.5%. Although the risk of congenital malformations increases with increasing HbA_{1c} levels, there may still be an increased risk in the therapeutic goal range. Congenital anomalies of the central nervous system and cardiovascular system are most common, including failure of neural tube closure (encephalocele, meningomyelocele, and anencephaly), transposition of great vessels, ventricular septal defect (VSD), atrial septal defect (ASD), hypoplastic left heart, aortic stenosis, and coarctation of the aorta. Other, less common anomalies include caudal regression syndrome, intestinal atresia, renal agenesis, hydronephrosis, and cystic kidneys. **Small left colon syndrome** is a rare anomaly that develops in the second and third trimester because of rapid fluctuations in maternal and therefore fetal glucose, leading to impaired intestinal motility and subsequent intestinal growth. Prenatal ultrasound and a thorough newborn physical examination will identify most of these anomalies. High clinical suspicion and a good prenatal history will help identify needed screening for subtle anomalies.

Treatment

Preventive treatment of IDMs should be initiated before birth by means of preconception and frequent prenatal evaluations of all women with preexisting diabetes and pregnant women with gestational diabetes. This involves evaluation of fetal maturity, biophysical profile, Doppler velocimetry, and planning of the delivery of IDMs in hospitals where expert obstetric and pediatric care is continuously available. Preconception glucose control reduces the risk of anomalies and other adverse outcomes in women with pregestational diabetes, and glucose control during labor reduces the incidence of neonatal hypoglycemia. Women with type 1 diabetes who have tight glucose control during pregnancy (average daily glucose levels <95 mg/dL) deliver infants with birthweight and anthropomorphic features similar to those of infants of nondiabetic mothers. Treatment of gestational diabetes (diet, glucose monitoring, metformin, and insulin therapy as needed) decreases the rate of serious perinatal outcomes (death, shoulder dystocia, bone fracture, or nerve palsy). Women with gestational diabetes may also be treated successfully with **glyburide** , which may not cross the placenta. In these mothers, the incidence of macrosomia and neonatal hypoglycemia is similar to that in mothers with insulin-treated gestational diabetes. Women with diabetes can begin to express breast milk before the birth of the baby (≥36 wk gestational age); this will provide an immediate supply of milk to prevent hypoglycemia.

Regardless of size, IDMs should initially receive close observation and care (Fig. 127.3). Infants should initiate feedings within 1 hr after birth. A screening glucose test should be performed within 30 min of the first feed. Transient **hypoglycemia** is common during the 1st 1-3 hr after birth and may be part of normal adaptation to extrauterine life. The target plasma glucose concentration is ≥40 mg/dL before feeds in the 1st 48 hr of life. Clinicians need to assess the overall metabolic and physiologic status, considering these in the management of hypoglycemia. Treatment is indicated if the plasma glucose is <47 mg/dL.

Feeding is the initial treatment for *asymptomatic* hypoglycemia. Oral or gavage feeding with breast milk or formula can be given. An alternative is prophylactic use of **dextrose** gel, although early feedings may be equally effective. Recurrent hypoglycemia can be treated with repeat feedings or IV glucose as needed. Infants with *persistent* (and unresponsive to oral therapy) glucose levels <25 mg/dL during the 1st 4 hr after birth and <35 mg/dL at 4-24 hr after birth should be treated with IV glucose, especially if symptomatic. A small bolus of 200 mg/kg of dextrose (2 mL/kg of 10% dextrose) should be administered to infants with plasma glucose below these limits. The small bolus should be followed by a continuous IV glucose infusion to avoid hypoglycemia. If question arises about an infant's ability to tolerate oral feeding, a continuous peripheral IV infusion at a rate of 4-8 mg/kg/min should be given. Neurologic symptoms of hypoglycemia *must* be treated with IV glucose. Bolus injections of hypertonic (25%) glucose should be avoided because they may cause further hyperinsulinemia and potentially produce rebound hypoglycemia (see Chapter 111). For treatment of hypocalcemia and hypomagnesemia, see Chapters 119.4 and 119.5 ; for RDS treatment, see Chapter 122.3 ; and for treatment of polycythemia, see Chapter 124.3 .



Able to feed
Yes
No
Breastfeed within 1 hr
Admit to NICU for IV glucose
Measure blood glucose at 1-2 hr of age
Glucose ≥ 45 mg/dL²
Glucose 20-45 mg/dL
Glucose < 20 mg/dL
Measure glucose 3-4 times before feeds¹
0.5 mL/kg oral 40% dextrose gel then breastfeed
Admit to NICU for IV glucose Consider administering a dose of 0.5 mL/kg 40% dextrose gel while arranging admission
Recheck blood glucose in 30 min
Glucose ≥ 45 mg/dL²
Glucose 20-45 mg/dL
Glucose < 20 mg/dL
Measure glucose 3-4 times before feeds¹
0.5 mL/kg oral 40% dextrose gel then breastfeed
Admit to NICU for IV glucose Consider administering a dose of 0.5 mL/kg 40% dextrose gel while arranging admission
Recheck blood glucose in 30 min
Glucose ≥ 45 mg/dL²
Glucose 36-45 mg/dL
Glucose < 36 mg/dL
Measure glucose 3-4 times before feeds¹
Formula or EBM 90 mL/kg/day
Admit to NICU for IV glucose Consider administering a dose of 0.5 mL/kg 40% dextrose gel while arranging admission
Recheck blood glucose in 1 hour
Admit to NICU if glucose remains < 45 mg/dL

FIG. 127.3 Screening algorithm for *asymptomatic* hypoglycemia during first day of life among at-risk infants. Screening is indicated for late preterm infants, those who are small for gestational age/intrauterine growth restriction, and infants of obese or diabetic mothers. [1] Continue monitoring blood glucose concentrations until 3 consecutive blood glucose concentrations have been ≥45-50 mg/dL. [2] There is no consensus for a threshold definition for neonatal hypoglycemia in the first day of life. Nonetheless, if the blood glucose is less than 45-50 mg/dL **AND** symptoms compatible with hypoglycemia are present (see text), treatment must be initiated with an IV minibolus of 10% glucose at 200 mg/kg **followed** by a continuous IV infusion of glucose at a starting rate of 5-8 mg/kg/min. IV, Intravenous; EBM, expressed breast milk. (Modified from Newborn Services Clinical Guidelines for the Management of Hypoglycaemia http://www.adhb.govt.nz/newborn/Guidelines/Nutrition/HypoglycaemiaManagement.htm .)

Prognosis

The subsequent incidence of diabetes mellitus in IDMs is higher than that in the general population because of genetic susceptibility in all types of diabetes. Infants of mothers with either pregestational diabetes or gestational diabetes are at risk for obesity and impaired glucose metabolism in later life as a result of intrauterine exposure to hyperglycemia. Disagreement persists about whether IDMs have a slightly increased risk of impaired intellectual development because of the many confounding factors (e.g., parental education, maternal age, neonatal complications). In general, the outcomes have improved over the last several decades due to increased awareness, screening, and improved prenatal care for pregnant women with diabetes.

CHAPTER 128

Dysmorphology

Anne M. Slavotinek

Dysmorphology is the study of differences in human form and the mechanisms that cause them. It has been estimated that 1 in 40 newborns, or 2.5%, have a recognizable birth defect or pattern of malformations at birth; approximately half these newborns have a single, isolated malformation, whereas in the other half, multiple malformations are present. From 20–30% of infant deaths and 30–50% of deaths after the neonatal period are caused by congenital abnormalities (http://www.marchofdimes.com/peristats/). In 2001, birth defects accounted for 1 in 5 infant deaths in the United States, with a rate of 137.6 deaths per 100,000 live births, which was higher than other causes of mortality, such as preterm/low birthweight (109.5/100,000), sudden infant death syndrome (55.5/100,000), maternal complications of pregnancy (37.3/100,000), and respiratory distress syndrome (25.3/100,000).

Classification of Birth Defects

Birth defects can be subdivided into isolated (single) defects or multiple congenital anomalies (multiple defects) in one individual. An isolated primary defect can be classified, according to the nature of the presumed cause of the defect, as a malformation, dysplasia, deformation, or disruption (Table 128.1 and Fig. 128.1). Most birth defects are malformations. A **malformation** is a structural defect arising from a localized error in morphogenesis that results in the abnormal formation of a tissue or organ. **Dysplasia** refers to the abnormal organization of cells into tissues. Malformations and dysplasias can both affect intrinsic structure. In contrast, a **deformation** is an alteration in shape or structure of a structure or organ that has developed, or differentiated, normally. A **disruption** is a defect resulting from the destruction of a structure that had formed normally before the insult.

Table 128.1

Mechanisms, Terminology, and Definitions of Dysmorphology

TERMINOLOGY	DEFINITION	EXAMPLE
Sequence	Single error in morphogenesis that results in a series of subsequent defects	Pierre-Robin sequence, in which a small jaw results in glossoptosis and cleft palate DiGeorge sequence of primary 4th brachial arch and 3rd and 4th pharyngeal pouch defects, leading to aplasia or hypoplasia of the thymus and parathyroid glands, aortic arch anomalies, and micrognathia
Deformation sequence	Mechanical (uterine) force that alters structure of intrinsically normal tissue	Oligohydramnios produces deformations by in utero compression of limbs (e.g., dislocated hips, equinovarus foot deformity), crumpled ears, or small thorax
Disruption sequence	In utero tissue destruction after a period of normal morphogenesis	Amnionic membrane rupture sequence, leading to amputation of fingers/toes, tissue fibrosis, and tissue bands
Dysplasia sequence	Atypical organization of cells into tissues or organs	Neurocutaneous melanosis sequence, with atypical migration of melanocyte precursor cells from the neural crest to the periphery, manifesting as melanocytic hamartomas of skin and meninges
Malformation syndrome	Appearance of multiple malformations in unrelated tissues that have a known, unifying cause	Trisomy 21 Teratogens Numerous multiple congenital anomaly syndromes as described above

From Kliegman RM, Greenbaum LA, Lye PS: *Practical strategies in pediatric diagnosis and therapy* , ed 2, Philadelphia, 2004, Elsevier Saunders.

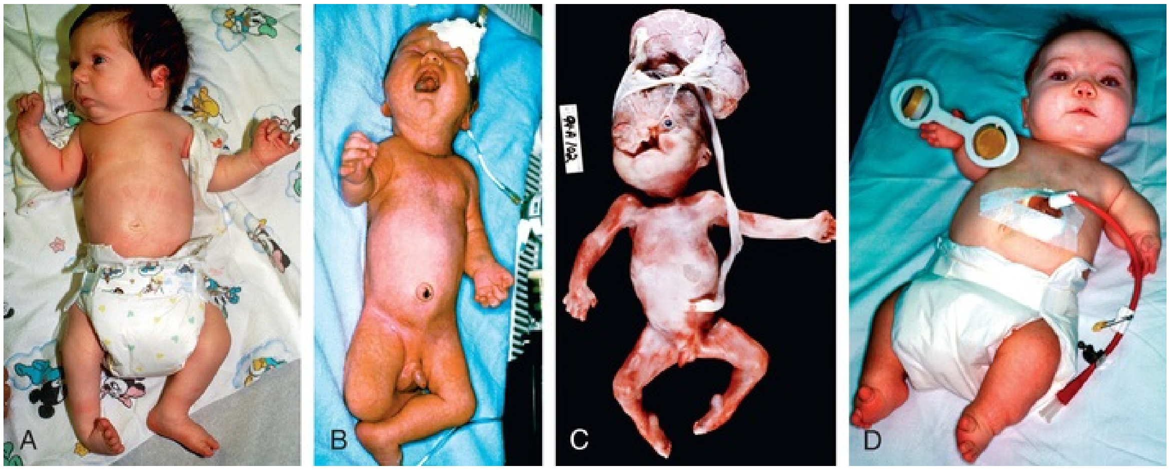

FIG. 128.1 **Four major types of problems in morphogenesis: malformation, deformation, disruption, and dysplasia. A, Infant with camptomelic dysplasia syndrome, which results in a multiple malformation syndrome caused by a mutation in *SOX9* . B, Infant with oligohydramnios deformation sequence caused by premature rupture of membranes from 17 wk gestation until birth at 36 wk; the infant was delivered from**

persistent transverse lie. C, Fetus with early amnion rupture sequence with attachment of the placenta to the head and resultant disruption of craniofacial structures with distal limb contractures. D, Infant with diastrophic dysplasia caused by inherited autosomal recessive mutations in a sulfate transporter protein. (From Graham Jr JM: *Smith's recognizable patterns of human deformation,* ed 3, Philadelphia, 2007, Saunders, Fig 1-1, p 4.)

Most inherited human disorders with altered morphogenesis display multiple malformations rather than isolated birth defects. When several malformations coexist in a single individual, they can be classified as a syndrome, sequence, or an association. A **syndrome** is defined as a pattern of multiple abnormalities that are related by pathophysiology, resulting from a single, defined etiology. **Sequences** consist of multiple malformations that are caused by a single event, although the sequence itself can have different etiologies. An **association** refers to a nonrandom grouping of malformations in which there is an unclear, or unknown, relationship among the malformations, such that they do not fit the criteria for a syndrome or sequence.

Malformations and Dysplasias

Human malformations and dysplasias can be caused by gene mutations, chromosome aberrations and copy number variants, environmental factors, or interactions between genetic and environmental factors (Table 128.2). Some malformations are caused by deleterious sequence variants in single genes, whereas other malformations arise because of deleterious sequence variants in multiple genes acting in combination (*digenic* or *oligogenic* inheritance). In 1996 it was thought that malformations were caused by monogenic defects in 7.5% of patients; chromosomal anomalies in 6%; multigenic defects in 20%; and known environmental factors, such as maternal diseases, infections, and teratogens, in 6–7% (Table 128.3). In the remaining 60–70% of patients, malformations were classified as caused by unknown etiologies. Currently, the percentages have increased for all categories of known causes of malformations, the result of improved cytogenetic and molecular genetic methods for detecting small chromosomal abnormalities and next-generation sequencing studies that can screen multiple genes simultaneously and identify novel genes and deleterious sequence variants.

Table 128.2

Examples of Malformations with Distinct Causes, Clinical

Features, and Pathogenesis

DISORDER	CAUSE/INHERITANCE	SELECTED CLINICAL FEATURES	PATHOGENESIS
Spondylocostal dysostosis syndrome	Mendelian; autosomal recessive	Abnormal vertebral and rib segmentation	Deleterious sequence variants in *DLL3* and other genes
Rubinstein-Taybi syndrome	Autosomal dominant	Intellectual disability Broad thumbs and halluces; valgus deviation of these digits Hypoplastic maxillae Prominent nose and columella Congenital heart disease	Deleterious sequence variants in *CBP* and *EP300*
X-linked lissencephaly	X-linked	Male: severe intellectual disability, seizures Female: variable	Deleterious sequence variants in *DCX*
Aniridia	Autosomal dominant	Absent iris or iris/foveal hypoplasia	Deleterious sequence variants in *PAX6*
Waardenburg syndrome, type I	Autosomal dominant	Deafness White forelock Wide-spaced eyes Iris heterochromia and/or pale skin pigmentation	Deleterious sequence variants in *PAX3*
Holoprosencephaly	Loss of function or heterozygosity for multiple genes	Microcephaly Cyclopia Single central incisor	*SHH*, multiple other genes
Velocardiofacial syndrome	Microdeletion 22q11.2	Congenital heart disease, including conotruncal defects Cleft palate T-cell defects Facial anomalies	*TBX1* haploinsufficiency/mutations; haploinsufficiency for other genes in the deleted interval also contributes to the phenotype.
Down syndrome	Additional copy of chromosome 21 (trisomy 21)	Intellectual disability Characteristic dysmorphic features Congenital heart	Increase in dosage of an estimated 250 genes on chromosome 21

		disease	
		Increased risk of leukemia	
		Alzheimer disease	
Neural tube defects	Multifactorial	Meningomyelocele	Defects in folate sensitive enzymes or folic acid uptake
Fetal alcohol syndrome	Teratogenic	Microcephaly	Ethanol toxicity to developing brain
		Developmental delay	
		Facial abnormalities	
		Behavioral abnormalities	
Retinoic acid embryopathy	Teratogenic	Microtia	Isotretinoin effects on neural crest and branchial arch development
		Congenital heart disease	

Table 128.3

Causes of Congenital Malformations

MONOGENIC
X-linked hydrocephalus Achondroplasia Ectodermal dysplasia Apert syndrome Treacher Collins syndrome
CHROMOSOMAL ABERRATIONS and COPY NUMBER VARIANTS
Trisomy 21, 18, 13 XO, XXY Deletions 4p−, 5p−, 7q−, 13q−, 18p−, 18q−, 22q− Prader-Willi syndrome (70% of affected patients have deletion of chromosome 15 q11.2-q13)
MATERNAL INFECTION
Intrauterine infections (e.g., herpes simplex virus, cytomegalovirus, varicella-zoster virus, rubella virus, Zika virus, toxoplasmosis)
MATERNAL ILLNESS
Diabetes mellitus Phenylketonuria Hyperthermia
UTERINE ENVIRONMENT
Deformation Uterine pressure, oligohydramnios: clubfoot, torticollis, congenital hip dislocation, pulmonary hypoplasia, 7th nerve palsy Disruption Amniotic bands, congenital amputations, gastroschisis, porencephaly, intestinal atresia Twinning
ENVIRONMENTAL AGENTS
Polychlorinated biphenyls Herbicides Mercury Alcohol
MEDICATIONS
Thalidomide

Diethylstilbestrol Phenytoin Warfarin Cytotoxic drugs Paroxetine Angiotensin-converting enzyme inhibitors Isotretinoin (vitamin A) D-Penicillamine Valproic acid Mycophenolate mofetil
UNKNOWN ETIOLOGIES
Neural tube defects, such as anencephaly and spina bifida Cleft lip/palate Pyloric stenosis
SPORADIC SEQUENCE COMPLEXES
VATER/VACTERL sequence (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula with esophageal atresia, radial and renal anomalies) Pierre Robin sequence
NUTRITIONAL
Neural tube defects due to low folic acid

From Behrman RE, Kliegman RM, editors: *Nelson's essentials of pediatrics,* ed 4, Philadelphia, 2002, Saunders.

Many developmental abnormalities that are caused by deleterious sequence variants (mutations)in a single gene display characteristic, mendelian patterns of inheritance (autosomal dominant, autosomal recessive, and X-linked inheritance). Genes that cause birth defects or multiple congenital anomaly syndromes are often transcription factors, part of evolutionarily conserved signal transduction pathways, or regulatory proteins required for key developmental events (Figs. 128.2 and 128.3). Examples include spondylocostal dysostosis syndromes, Smith-Lemli-Opitz syndrome, Rubinstein-Taybi syndrome, and X-linked lissencephaly (“smooth brain”) syndrome (see Table 128.2).

FIG. 128.3 **The RAS/MAPK signal transduction pathway. The MAPK signaling pathway of protein kinases is critically involved in cellular proliferation, differentiation, motility, apoptosis, and senescence. The RASopathies are medical genetic syndromes caused by mutations in genes that encode components or regulators of the Ras/MAPK pathway (indicated by *dashed lines*). These disorders include neurofibromatosis type 1 (NF1), Noonan syndrome (NS), Noonan syndrome with multiple lentigines (NSML), capillary malformation–arteriovenous malformation syndrome (CM-AVM), Costello syndrome (CS), cardiofaciocutaneous syndrome (CFC), and Legius syndrome. RAS/MAPK, RAS protein family/mitogen-activated protein kinase. (From Rauen KA: The RASopathies, *Annu Rev Genom Hum Genet* 14:355–369, 2013.)**

Patients with **spondylocostal dysostosis (SCD)** display a characteristic pattern of vertebral segmentation defects associated with a number of other malformations, such as neural tube defects. The **SCD syndromes** are etiologically heterogeneous and are often caused by mutations in the gene coding for delta-like 3 (*DLL3*), a ligand of the Notch receptors. The Notch/delta pathway is conserved throughout evolution and regulates a number of developmental events. **Smith-Lemli-Opitz syndrome (SLOS)** results from mutations in the sterol delta-7-dehydrocholesterol reductase (*DHCR7*) gene, an enzyme critical for normal cholesterol biosynthesis. Patients with SLOS (see Fig. 128.2) display syndactyly (fusion of the fingers and toes), in particular affecting the 2nd and 3rd toes; postaxial polydactyly (extra digits); anteverted (upturned) nose; ptosis; cryptorchidism; and holoprosencephaly (failure of separation of the 2 cerebral hemispheres). Many of the features in SLOS are shared with those arising from deleterious sequence variants in the *SHH* genes, and these mutations link cholesterol biosynthesis pathogenically to the sonic hedgehog (SHH) pathway, because SHH is posttranslationally modified by cholesterol (see Chapter 97). **Rubinstein-Taybi syndrome** (see Fig. 128.2) typically results from heterozygous, loss-of-function deleterious sequence variants in a gene coding for a broadly acting transcriptional coactivator called *CREB-binding protein* (CBP) and from deleterious sequence variants in the *EP300* gene. The CBP coactivator regulates the transcription of a number of genes, which is why patients with deleterious sequence variants in *CBP* have a pleiotropic phenotype that includes developmental delays and intellectual disability, broad and angulated thumbs and halluces (1st toes), and congenital heart disease. One of the transcription factors that binds to CBP is *GLI3,* a member of the SHH pathway (see Fig. 128.2). **X-linked lissencephaly** is a severe neuronal migration defect that causes a smooth brain with reduction or absence of gyri and sulci in males and that gives rise to a variable pattern of intellectual disability and seizures in females. X-linked lissencephaly is caused by deleterious sequence variants in *DCX* . The DCX protein regulates the activity of dynein motors that contribute to movement of the cell nucleus during neuronal migration.

Malformation syndromes can also be caused by chromosomal aberrations or copy number variants and teratogens (see Tables 128.2 and 128.3). **Down syndrome** typically results from an extra copy of an entire chromosome 21 or, less frequently, an extra copy of the Down syndrome critical region on chromosome 21. Chromosome 21 is a small chromosome that contains an estimated 250 genes, and thus individuals with Down syndrome typically have an increased dosage of the numerous genes encoded by this chromosome that causes their physical differences (see Chapter 98.2).

Neural tube defects (NTDs) are an example of a birth defect that displays multifactorial inheritance in most cases. NTDs and a number of other congenital malformations, such as cleft lip and palate, can recur in families, but inheritance for the majority of affected individuals does not occur in a straightforward, mendelian inheritance pattern, and in this situation, multiple genes and environmental factors together likely contribute to the pathogenesis (see Table 128.2). Many of the genes involved in NTDs are unknown, so one cannot predict with certainty the mode of inheritance or a precise recurrence risk in the individual case. Empirical recurrence risks can be provided on the basis of population studies and the presence of single or multiple family members with the same malformation. However, one important gene/environment interaction has been identified for NTDs (see Chapter 609.1). **Folic acid deficiency** is associated with NTDs and can result from a combination of dietary factors and increased utilization during pregnancy. A common variant in the gene for an enzyme in the folate recycling pathway, 5,10-methylene-tetrahydrofolate reductase (*MTHFR*), that makes this enzyme less stable, may also be important in folic acid status. Several teratogenic causes of birth defects have been described (see Tables 128.2 and 128.3). **Ethanol** causes a recognizable malformation syndrome that is variably called fetal alcohol syndrome (FAS), fetal alcohol spectrum disorder (FASD), or fetal alcohol effects (FAE) (see Chapter 126.3). Children who were exposed to ethanol during the pregnancy can display microcephaly, developmental delays, hyperactivity, and facial dysmorphic features. Ethanol, which is toxic to the developing central nervous system (CNS), causes cell death in developing neurons.

Deformations

Many deformations involve the musculoskeletal system (Fig. 128.4). Fetal movement is required for the proper development of the musculoskeletal system, and restriction of fetal movement can cause musculoskeletal deformations such as clubfoot (talipes). Two major intrinsic causes of deformations are primary neuromuscular disorders and **oligohydramnios,** or decreased amniotic fluid, which can be caused by fetal renal defects. The major extrinsic causes of deformation are those that result in fetal crowding and restriction of fetal movement. Examples of extrinsic causes include oligohydramnios resulting from chronic leakage of amniotic fluid and abnormal shape of the amniotic cavity. When a fetus is in the breech position (Fig. 128.5), the incidence of deformations is increased 10-fold. The shape of the amniotic cavity also has a profound effect on the shape of the fetus and is influenced by many factors, including uterine shape, volume of amniotic fluid, and the size and shape of the fetus (Fig. 128.6).

It is important to determine whether deformations result from intrinsic or extrinsic causes. Most children with deformations from *extrinsic* causes are otherwise completely normal, and their prognosis is usually excellent. Correction typically occurs spontaneously. Deformations caused by *intrinsic* factors, such as multiple joint contractures resulting from CNS or peripheral nervous system defects, have a different prognosis and may be much more significant for the child (Fig. 128.7).

Disruptions

Disruptions are caused by destruction of a previously normally formed organ or body part. At least 2 mechanisms are known to produce disruptions. One involves entanglement, followed by tearing apart or amputation, of a normally developed structure, usually a digit or limb, by strands of amnion floating within amniotic fluid (amniotic bands) (Fig. 128.8). The other mechanism involves interruption to the blood supply to a developing part, which can lead to infarction, necrosis, and resorption of structures distal to the insult. If interruption to the blood supply occurs early in gestation, the disruptive defect typically involves **atresia,** or absence of a body part. Genetic factors were previously considered to play a minor role in the pathogenesis of disruptions; most occur as sporadic events in otherwise healthy individuals. The prognosis for a disruptive defect is determined entirely by the extent and location of the tissue loss.

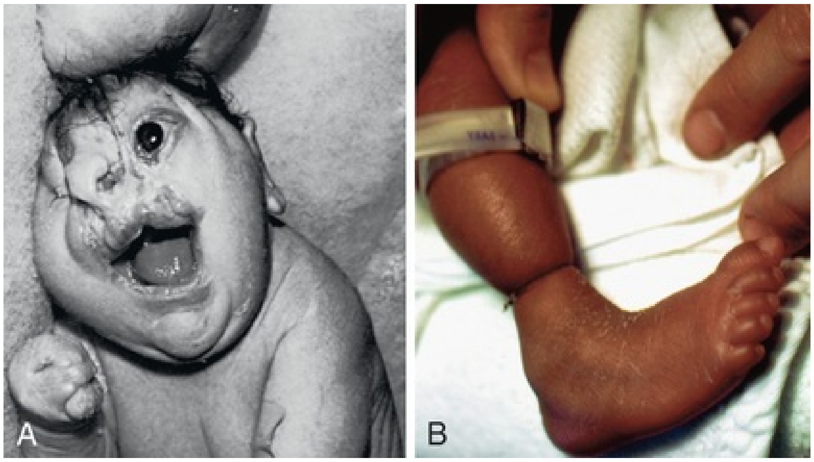

FIG. 128.8 **A,** Amniotic band disruption sequence. **B,** Bands constricting the ankle leading to deformational defects and amputations. (From Jones KJ: *Smith's recognizable patterns of human malformation,* ed 6, Philadelphia, 2006, Saunders.)

Multiple Anomalies: Syndromes and Sequences

The pattern of multiple anomalies that occurs when a single primary defect in early development produces multiple abnormalities because of a cascade of secondary and tertiary developmental anomalies is called a *sequence* (see Fig. 128.9). When evaluating a child with multiple congenital anomalies, the physician must differentiate between multiple anomalies that are caused by a single localized error in morphogenesis (a sequence) from syndromes with multiple malformations. In the former, recurrence risk counseling for the multiple anomalies depends entirely on the risk of recurrence for the single, localized malformation. **Pierre-Robin sequence** is a pattern of multiple anomalies produced by mandibular hypoplasia. Because the tongue is relatively large for the oral cavity, it drops back (glossoptosis), blocking closure of the posterior palatal shelves and causing a U -shaped cleft palate. There are numerous causes of mandibular hypoplasia, all of which can result in characteristic features of Pierre-Robin sequence.

Molecular Mechanisms of Malformations

Inborn Errors of Development

Genes that cause malformation syndromes (as well as genes whose expression is disrupted by environmental agents or teratogens) can be part of numerous cellular processes, including evolutionarily conserved signal transduction pathways, transcription factors, or regulatory proteins required for key developmental events. When malformations are considered as alterations resulting from disturbances to important developmental pathways, this provides a molecular framework for understanding the birth defects.

Sonic Hedgehog Pathway As Model

The SHH pathway is developmentally important during embryogenesis to induce controlled proliferation in a tissue-specific manner; disruption of specific steps in this pathway results in a variety of related developmental disorders and malformations (see Fig. 128.2). Activation of this pathway in the adult leads to abnormal proliferation and cancer. The SHH pathway transduces an external signal, in the form of a *ligand,* into changes in gene transcription by binding of the ligand to specific cellular receptors. SHH is a ligand expressed in the embryo in regions important for development of the brain, face, limbs, and the gut.

Deleterious sequence variants in *SHH* can cause **holoprosencephaly** (see Fig. 128.2), a variably severe, midline defect associated with clinical effects ranging from cyclopia to a single maxillary incisor with hypotelorism or close spacing of the ocular orbits. The SHH protein is processed by proteolytic cleavage to an active N-terminal form, which is then further modified by the addition of cholesterol. Defects in cholesterol biosynthesis, in particular the sterol, delta-7-dehydrocholesterol reductase gene, result in **SLOS** , which is also associated with holoprosencephaly. The modified and active form of SHH binds to its transmembrane receptor Patched (PTCH1). SHH binding to PTCH1 inhibits the activity of the transmembrane protein Smoothened (SMO). SMO act to suppress downstream targets of the SHH pathway, the GLI family of transcription factors, so inhibition of SMO by PTCH1 results in activation of GLI1, GLI2, and GLI3, resulting in alteration of transcription of GLI targets. *PTCH1* and its orthologue, *PTCH2* , can act as tumor suppressors, and somatic, inactivating sequence variants can be associated with loss of tumor suppressor function, whereas activating mutations in *SMO* can also be oncogenic, particularly in basal cell carcinomas and medulloblastomas. Germline, inactivating mutations in *PTCH1* result in **Gorlin syndrome** (see Fig. 128.4), an autosomal dominant disorder characterized by dysmorphic features (broad face, dental anomalies, rib defects, short metacarpals), basal cell nevi that can undergo malignant transformation, and an increased risk of cancers, including medulloblastomas and rhabdomyosarcomas. *GLI1* amplification has been found in several human tumors, including glioblastoma, osteosarcoma, rhabdomyosarcoma, and B cell lymphomas; mutations or alterations in *GLI3* have been found in **Greig cephalopolysyndactyly syndrome** (GCPS), **Pallister-Hall syndrome (** PHS), postaxial polydactyly type A (and A/B), and preaxial polydactyly type IV (see Fig. 128.2). GCPS consists of hypertelorism (wide-spaced eyes), syndactyly, preaxial polydactyly, and broad thumbs and halluces. PHS is an autosomal dominant disorder characterized by postaxial polydactyly, syndactyly, hypothalamic hamartomas, imperforate anus, and occasionally holoprosencephaly. GLI3 binds to CBP, the protein that is haploinsufficient in **Rubinstein-Taybi syndrome** .

Disorders that are caused by mutations in genes that function together in a developmental pathway typically have overlapping clinical manifestations. In this case, the overlapping features result from the expression domains of SHH that are important for development of the brain, face, limbs, and gut. Brain defects are found in holoprosencephaly (Fig. 128.9), SLOS, and PHS. Facial abnormalities are found in holoprosencephaly, SLOS, Gorlin syndrome, GCPS, and PHS. Limb defects are found in SLOS, Gorlin syndrome, GCPS, PHS, and the polydactyly syndromes. Overexpression, or activating mutations, affecting the SHH pathway results in cancer, including basal cell carcinomas, medulloblastomas, glioblastomas, and rhabdomyosarcomas.

The SHH pathway interaction with the primary cilium is critical to transduce the SHH extracellular signal through to the nuclear machinery. A number of disorders, including Bardet-Biedl syndrome, oral-facial-digital (OFD) syndrome type I, and Joubert syndrome, are caused by mutations in genes that function in the primary cilium. These disorders, called **ciliopathies** , overlap clinically with some of the phenotypic features described previously, again demonstrating that perturbations of conserved developmental pathways can cause overlapping presentations (Table 128.4).

Table 128.4

Childhood Diseases and Syndromes Associated with Motile and Sensory Ciliopathies

PEDIATRIC CILIOPATHY	CLINICAL MANIFESTATIONS	SELECTED GENE(S)
MOTOR		
Primary ciliary dyskinesia	Chronic bronchitis, rhinosinusitis, otitis media, laterality defects, infertility, CHD	*DNAI1, DNAH5, DNAH11, DNAI2, KTU, TXNDC3, LRRC50, RSPH9, RSPH4A, CCDC40, CCDC39*
SENSORY		
Autosomal recessive polycystic kidney disease	RFD, CHF	*PKHD1*
Nephronophthisis	RFD, interstitial nephritis, CHF, RP	*NPHP1-8, ALMS1, CEP290*
Bardet-Biedl syndrome	Obesity, polydactyly, ID, RP, renal anomalies, anosmia, CHD	*BBS1-12, MKS1, MKS3, CEP290*
Meckel-Gruber syndrome	RFD, polydactyly, ID, CNS anomalies, CHD, cleft lip, cleft palate	*MKS1-6, CC2D2A, CEP290, TMEM216*
Joubert syndrome	CNS anomalies, ID, ataxia, RP, polydactyly, cleft lip, cleft palate	*NPHP1, JBTS1, JBTS3, JBTS4, CORS2, AHI1, CEP290, TMEM216*
Alstrom syndrome	Obesity, RP, DM, hypothyroidism, hypogonadism, skeletal dysplasia, cardiomyopathy, pulmonary fibrosis	*ALMS1*
Orofaciodigital syndrome type I	Polydactyly, syndactyly, cleft lip, cleft palate, CNS anomalies, ID, RFD	*OFD1*
Ellis van Creveld syndrome	Chondrodystrophy, polydactyly, ectodermal dysplasia, CHD	*EVC, EVC2*
Jeune asphyxiating thoracic dystrophy	Narrow thorax, RFD, RP, dwarfism, polydactyly	*IFT80*
Sensenbrenner syndrome	Dolichocephaly, ectodermal dysplasia, dental dysplasia, narrow thorax, RFD, CHD	*IFT122, IFT43, WDR35*
Short rib–polydactyly syndromes	Narrow thorax, short limb dwarfism, polydactyly, renal dysplasia	*WDR35, DYNC2H1, NEK1*

CHD, Congenital heart disease; CHF, congenital hepatic fibrosis; CNS, central nervous system; DM, diabetes mellitus; ID, intellectual disabilities; RFD, renal fibrocystic disease; RP, retinitis pigmentosa.

Cytogenetic Aberrations and Chromosomal Imbalance

Cytogenetic imbalances resulting from an additional copy of a whole human chromosome can result in characteristic and recognizable syndromes. An additional copy of chromosome 21 results in **Down syndrome** (see Chapter 98.2); loss of one of the X chromosomes results in **Turner syndrome** (see Chapter 98 for discussion of syndromes with whole chromosomal imbalances). With the advent of high-resolution cytogenetic techniques, such as fluorescence in situ hybridization (FISH), array comparative genomic hybridization (array CGH), and single nucleotide polymorphism (SNP) arrays, it has become possible to identify **submicroscopic chromosome deletions and duplications** . A number of recurrent deletions and duplications have been identified that cause characteristic and recognizable syndromes, including **Williams syndrome** (deletion of chromosome 7q11.23), **Miller-Dieker syndrome** (deletion of chromosome 17p13.3), **Smith-Magenis syndrome** (deletion of chromosome 17p11.2), and 22q11 deletion syndrome (deletion of chromosome 22q11.2, also known as **velocardiofacial/DiGeorge syndrome**). Array CGH and SNP arrays have also made it possible to uncover rarer microdeletions and microduplications associated with birth defects, intellectual disability, and neuropsychiatric disorders. The sensitivity and specificity chromosome microarrays have made this the technique of choice for the initial evaluation of a child with multiple congenital anomalies and/or intellectual disability, although it is important to note that all individuals may carry numerous small microdeletions and microduplications as normal or familial variation. Therefore, it is important to compare copy number variants in these children with birth defects with their parents' chromosome analyses and with databases of normal variants detected in individuals without such birth defects.

Approach to the Dysmorphic Child

One approach to the dysmorphic child is the *pattern recognition* approach, which compares the manifestations in the patient against a broad and memorized (or computerized) knowledge of human pleiotropic disorders. Although this approach can be appropriate for a small number of experienced dysmorphologists, a systematic *genetic mechanism* approach can also be effective for clinicians who are not dysmorphology experts. By gathering and analyzing the clinical data, the general pediatrician can diagnose the patient in a straightforward case or initiate a referral to an appropriate specialist.

Medical History

The history for a patient with birth defects includes a number of elements related to etiologic factors. The *pedigree* or family history is necessary to assess the inheritance pattern, or lack thereof, for the disorder. For disorders that have a simple mendelian inheritance pattern, its recognition can be critical for narrowing the differential diagnosis, then prioritizing common genes with the appropriate inheritance pattern causing the patient's clinical features. A number of common birth defects have a complex or multifactorial genetic etiology, such as isolated cleft palate and spina bifida. The recognition of a close relative affected with a birth defect that is similar to that in the proband can be useful. Typically, a 3-generation pedigree is sufficient for this purpose (see Chapter 97).

The perinatal history is also an essential component of the history. It includes the pregnancy history of the mother (useful for recognition of recurrent miscarriages that may be indicative of a chromosomal disorder), factors that may relate to deformations or disruptions (oligohydramnios), and maternal exposures to teratogenic drugs or chemicals (isotretinoin and ethanol are potential causes of microcephaly).

Another component of the history that is often useful is the natural history of the **phenotype** . Malformation syndromes caused by chromosomal aberrations and single-gene disorders are frequently *static,* meaning that, although the patients can experience new complications over time, the phenotype is typically not progressive. In contrast, disorders that cause dysmorphic features because of metabolic perturbations (e.g., Hunter or Sanfilippo syndrome) can be mild or may not be apparent at birth, but they can progress relentlessly, causing deterioration of patient status over time.

Physical Examination

The physical examination is very important for the diagnosis of a dysmorphic syndrome. The essential element of the physical evaluation is an objective assessment of the patient's clinical findings. The clinician needs to perform an organized evaluation of the size and formation of various body structures. Familiarity with the nomenclature of dysmorphic signs is helpful (Table 128.5). The size and shape of the head is relevant; for example, many children with Down syndrome have mild microcephaly and brachycephaly (shortened anteroposterior dimension of skull). Eye position and shape are useful signs for many disorders. Reference standards are available with which physical measurements (e.g., interpupillary distance) can also be compared. It is also useful to categorize abnormalities as “major” or “minor” birth defects. Major defects either cause significant dysfunction (e.g., absence of a digit) or require surgical correction (e.g., polydactyly), and minor defects neither cause significant dysfunction nor require surgical correction (e.g, mild clinodactyly)

(Table 128.6 and Fig. 128.10). By cataloging physical parameters, the clinician may be able to recognize the diagnosis.

Table 128.5

Definitions of Common Clinical Signs of Dysmorphic Syndromes

SIGN	DEFINITION
Brachycephaly	A condition in which head shape is shortened from front to back along the sagittal plane; typically the back of the skull (occiput) and face are flatter than normal.
Brachydactyly	Short digits.
Brushfield spots	Speckled white spots or rings about two thirds of the distance to the periphery of the iris of the eye.
Camptodactyly	Permanent flexion of 1 or more fingers that can be associated with missing interphalangeal crease.
Clinodactyly	A medial or lateral curving of the fingers or toes; usually refers to incurving of the 5th finger.
Hypoplastic or small nail	A small nail on a digit.
Low-set ears	This designation is made when the helix meets the cranium at a level below a horizontal plane that is an extension of a line through both inner canthi.
Melia	A suffix meaning “limb” (e.g., amelia—missing limb; brachymelia—short limb).
Ocular hypertelorism or wide-set eyes	Increased distance between the center of the pupils of the 2 eyes; also known as *increased interpupillary distance* (IPD).
Plagiocephaly	A condition in which head shape is asymmetric in the sagittal or coronal plane; can result from asymmetry in cranial suture closure, asymmetry of brain growth, or deformation of the skull.
Posterior hair whorl	A single hair whorl occurs to the right or left of midline and is within 2 cm anterior to the posterior fontanel in 95% of cases.
Postaxial polydactyly	Extra finger or toe present on the lateral side of the hand or foot.
Preaxial polydactyly	Extra finger or toe present on the medial side of the hand or foot.
Prominent lateral palatine ridges	Relative overgrowth of the lateral palatine ridges that can be caused by a deficit of tongue thrust into the hard palate.
Scaphocephaly	A condition in which the head is elongated from front to back in the sagittal plane; most normal skulls are scaphocephalic; also termed *dolichocephaly* .
Shawl scrotum	The scrotal skin joins around the superior aspect of the penis and represents a mild deficit in full migration of the labial-scrotal folds.
Short palpebral fissures	Decreased horizontal distance of the eyelid folds based on measurements from the inner canthus to the outer canthus,
Syndactyly	Incomplete separation of the fingers or toes. It most commonly occurs between the 3rd and 4th fingers and between the 2nd and 3rd toes.
Synophrys	Eyebrows that meet in the midline.
Telecanthus	Lateral displacement of the inner canthi. The inner canthal distance (ICD) is increased, but the interpupillary distance (IPD) is normal.
Widow's peak	V -shaped midline, downward projection of the scalp hair in the frontal region. It represents an upper forehead intersection of the bilateral fields of periocular hair growth suppression. It usually occurs because the fields are widely spaced, as in ocular hypertelorism.

Table 128.6

Minor Anomalies and Phenotype Variants*

CRANIOFACIAL
Large anterior fontanel Flat or low nasal bridge Anteverted (upturned) nose Mild micrognathia Cutis aplasia of scalp
EYE
Epicanthus Telecanthus Slanting of the palpebral fissures Hypertelorism (widely spaced eyes) Brushfield spots
EAR
Lack of helical folds Posteriorly rotated pinna Small pinnae Auricular or preauricular pit Atypical folding of helices Crushed (crumpled) ear Asymmetric ear sizes Low-set ears
SKIN
Skin dimpling over bones Capillary hemangioma (face, posterior neck) Dermal melanosis (African Americans, Asians) Sacral dimple Pigmented nevi Redundant skin Cutis marmorata
HAND
Single palmar creases Bridged palmar creases Clinodactyly of 5th digits Hyperextensibility of thumbs Mild partial cutaneous syndactyly Polydactyly Short, broad thumb Narrow, hyperconvex nails Small nails Camptodactyly Shortened 4th digit
FOOT
Partial syndactyly of 2nd and 3rd toes Asymmetric toe length Clinodactyly of 2nd toe Overlapping toes Small nails Wide gap between hallux and 2nd toe (wide sandal gap) Deep plantar crease between hallux and 2nd toe

OTHER
Hydrocele
Shawl scrotum
Hypospadias
Hypoplasia of labia majora

[*] Approximately 15% of newborns have 1 minor anomaly, 0.8% have 2 minor anomalies, and 0.5% have 3. If 2 minor anomalies are present, the probability of an underlying syndrome or a major anomaly (congenital heart disease, renal, central nervous system, limbic) is 5-fold that in the general population. If 3 minor anomalies are present, there is a 20–30% probability of a major anomaly.

From Kliegman RM, Greenbaum LA, Lye PS: *Practical strategies in pediatric diagnosis and therapy* , ed 2, Philadelphia, 2004, Elsevier Saunders.

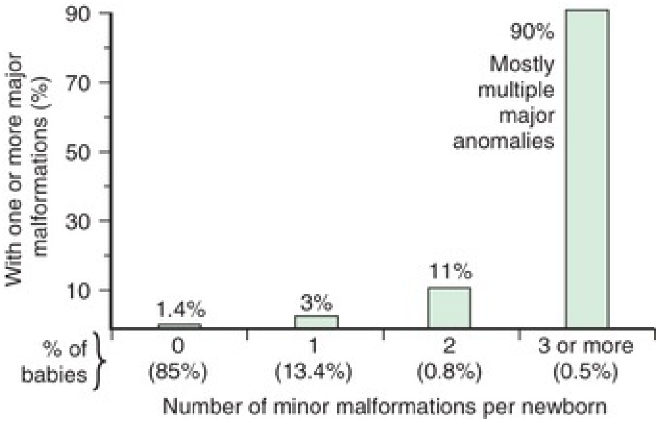

FIG. 128.10 Frequency of major malformations in relation to the number of minor anomalies detected in a given newborn baby. (From Jones KJ: *Smith's recognizable patterns of human malformation,* ed 6, Philadelphia, 2006, Saunders.)

Imaging Studies

Imaging studies can be critical in diagnosing an underlying genetic etiology. If short stature or disproportionate stature (e.g., long trunk and short limbs) is noted, a full skeletal survey with radiographs should be performed. The skeletal survey can detect anomalies in bone number or structure that can be used to narrow the differential diagnosis. When there are abnormal neurologic signs or symptoms, such as microcephaly or hypotonia, brain imaging can be indicated. Other studies, such as echocardiography and renal ultrasonography, can also be useful to identify additional major or minor malformations that may serve as diagnostic clues.

Diagnosis

The examining physician should gather data on the patient's pedigree and perinatal and pediatric (for older children) history and should have an appreciation for the natural history of the clinical findings. At this point, the physician has examined the child, identified atypical physical features, and obtained appropriate imaging studies.

The clinician should now attempt to organize the findings to elucidate potential developmental processes. An assessment based on **specificity** can be helpful for this process. If a child has multiple findings, such as a patent ductus arteriosus (PDA), mild growth restriction, mild microcephaly, and holoprosencephaly, micropenis, and ptosis, a selection of the rarer or pathognomonic findings may be prioritized. The PDA, ptosis, mild growth restriction, and mild microcephaly are considered to be largely *nonspecific findings* (present in many disorders or often present as isolated features that are not part of a syndrome), whereas holoprosencephaly and micropenis are present in fewer syndromes and are not considered part of normal variation. The clinician can therefore search for disorders that include both holoprosencephaly and micropenis. The search can be performed manually using the features index of a textbook such as *Smith's Recognizable Patterns of Human Malformation* or a computerized database such as Online Mendelian Inheritance in Man (OMIM). Searching for both holoprosencephaly and micropenis returns a list of diagnostic possibilities, and the physician can then return to the patient to examine for additional features of the leading possible candidate disorders. Appropriate genetic testing can then be undertaken to confirm the clinician's hypothesis and verify the diagnosis.

Laboratory Studies and Genetic Testing

The laboratory evaluation of the dysmorphic child can be critical to reach or confirm the correct diagnosis. Cytogenetic studies with Giemsa-banded (G-banded) chromosome analysis, or karyotyping, was the gold standard previously performed in the evaluation of a dysmorphic patient. Array CGH and SNP arrays enable copy number variant detection and, in the case of SNP arrays, evaluation of loss of heterozygosity. Chromosome deletion syndromes may also be identified with specific and sensitive FISH analysis (Table 128.7). These tests are the most sensitive methods for the detection of cytogenetic alterations associated with birth defects and multiple congenital anomalies.

Table 128.7

Chromosomal Deletion Syndromes

CONDITION	BRIEF DESCRIPTION	PROBE
Williams syndrome	Proportionate short stature, mild-moderate to severe intellectual disability, "cocktail patter" for conversation, stellate pattern of iris pigmentation, supravalvular aortic stenosis, recessed nasal bridge, and wide mouth with full lips	7q11
WAGR syndrome	Wilms tumor, aniridia, growth delay, intellectual disability, and genitourinary anomalies	11p13
Prader-Willi syndrome Angelman syndrome	Distinct syndromes with common or overlapping areas of deletion; phenotype depends on gender of the parent of origin of the deletion. Prader-Willi syndrome: hypotonia in infancy, short stature, obesity, mild-moderate and occasionally severe intellectual disability, small hands and feet (caused by paternal deletion of 15q11-13 or maternal uniparental disomy for chromosome 15) Angelman syndrome: severe intellectual disability, absence of speech, ataxia, tremulous movements, large mouth, frequent drooling (caused by maternal deletion of chromosome 15q11-13 or paternal uniparental disomy)	15q11
Smith-Magenis syndrome	Brachycephaly, prognathism, self-destructive behavior, wrist biting, pulling out nails, head banging, indifference to pain, severe intellectual disability, hyperactivity, social behavior problems	17p11.2
Miller-Dieker syndrome	Microcephaly, narrow temples, hypotonia/hypertonia, abnormal posturing, seizures, severe to profound intellectual disability, poor growth, lissencephaly and other brain abnormalities on CT or MRI	17p13
Velocardiofacial (VCF) syndrome (overlaps with DiGeorge syndrome)	VCF: cleft palate, congenital heart disease, learning/behavior problems, long face, prominent nose, limb hypotonia, slender hands with tapering fingers DiGeorge syndrome: T-cell deficiency, immunoglobulin deficiency	22q11

CT, Computed tomography; MRI, magnetic resonance imaging; WAGR, Wilms tumor, aniridia, genitourinary anomalies, and mental retardation.

From Kliegman RM, Lye PS, et al, editors: *Nelson pediatric symptom-based diagnosis,* Philadelphia, 2018, Elsevier (Table 25-10).

Molecular testing for deleterious sequence variants that cause pleiotropic malformation syndromes is also available for many disorders as clinical or research testing. In most cases, however, such testing should not be performed indiscriminately, but instead should be ordered thoughtfully after the differential diagnosis has been considered. The introduction of **next-generation sequencing** has led to the identification of innumerable novel genes and revolutionized the testing that is now available for patients and families with intellectual disability, birth defects, or other suspected genetic diseases. A strong suspicion of a genetic diagnosis warrants consideration of testing to confirm the diagnosis, facilitate patient treatment and anticipatory guidance, clarify recurrence risks, and enable carrier testing for relevant inheritance patterns. Single nucleotide variants, exons, or genes are tested by *Sanger sequencing* targeting single or multiple exons. However, for diagnoses that have substantial genetic heterogeneity (e.g., hearing loss), *panel testing,* in which multiple relevant genes can be interrogated for single nucleotide variants, gene deletions, and gene duplications, is more expeditious than Sanger sequencing. Panel tests also frequently have the advantage of providing high coverage for the genes on the panel, compared to coverage for the same genes obtained by exome sequencing. However, in situations with diagnostic uncertainty, such as the investigation of a child with intellectual disability and dysmorphic features, for which there is no clinically recognizable pattern, exome sequencing may be most useful as a broad testing approach. **Whole exome sequencing** (WES) examines approximately 200,000 exons, or the 1–2% of the DNA that comprises the coding regions of the genome. WES is typically performed with a *trio* approach, in which the patient and both biological parents are tested simultaneously, so that the inheritance pattern, or segregation, of deleterious sequence variants can be determined, thus simplifying analysis. Trio sequencing has resulted in higher diagnostic yields than proband-only sequencing and can approach 30–40% for indications such as intellectual disability. In contrast, **whole genome sequencing** (WGS) examines all the DNA content, including noncoding regions, and includes analysis for cytogenetic rearrangements in addition to copy number loss or gain. WES and WGS are applicable to a wide range of birth defects and genetic diseases and can discover causative variants in known or novel genes associated with a particular condition.

Management and Counseling

Management of the affected patient and genetic counseling are essential aspects of the approach to the dysmorphic patient. Children with Down syndrome have a high incidence of hypothyroidism, and children with achondroplasia have a high incidence of cervicomedullary junction abnormalities. One of the many benefits of an early and accurate diagnosis is that **anticipatory guidance and medical monitoring** of patients for syndrome-specific medical risks can prolong and improve their quality of life. When a diagnosis is made, the treating physicians can access published information on the natural history and management of the disorder through published papers, genetics reference texts, and databases.

The 2nd major benefit of an accurate diagnosis is that it provides data for appropriate **recurrence risk** estimates. Genetic disorders may have direct effects on only 1 member of the family, but the diagnosis of the condition can have implications for the entire family. One or both parents may be carriers; siblings may be carriers or may want to know their genetic status when they reach their reproductive years. Recurrence risk provision is an important component of genetic counseling and should be included in all evaluations for families affected with birth defects or other inherited disorders (see Chapter 94).

CHAPTER 129

Epidemiology of Infections

David B. Haslam

Infections in the newborn are often classified by their timing relative to birth and include congenital, perinatal, early-onset, and late-onset disease. These are clinically useful designations because the mechanisms of infection, etiologies, and outcomes are distinct at each stage. **Congenital infection** denotes infection acquired in utero. Such infections are generally caused by viral or other non-bacterial organisms and are often associated with injury to developing organs (see Chapter 131). **Perinatal infection** indicates acquisition around the time of delivery. Perinatally acquired organisms include both bacteria and viruses, some of which are the same as those causing congenital infection but often manifest with different features. **Early-onset infection** occurs in the 1st wk of life and is generally the consequence of infection caused by organisms acquired during the perinatal period. **Late-onset infection** occurs between 7 and 30 days of life and may include bacteria, viruses, or other organisms that are typically acquired in the postnatal period. **Hospital-acquired infections** typically occur beyond the 1st wk of life (see Chapter 130).

Neonates are uniquely prone to invasive disease because of their lack of fully responsive innate immunity (Fig. 129.1). Attenuated immune responses often result in minimal or nonspecific clinical manifestations, and effective treatment requires attention to subtle signs of infection. Compared to older infants, newborns are often treated empirically while awaiting results of laboratory investigations. Preterm infants are particularly susceptible to infection because of their decreased innate immune and barrier defenses and their prolonged stay in hospital settings.

Treg cells

FIG. 129.1 Ontogeny of skin, soluble, and cellular innate defense systems. Host-protective barrier functions include physical, chemical, and functional components of the skin and mucous membrane epithelia of the fetus, neonate (birth to 28 days of age), and infant (1 mo to 1 yr of age). Skin: while physical and chemical barriers are impaired in early in life, especially in the preterm newborn, the vernix caseosa and skin epithelia of full-term newborns robustly express antimicrobial proteins and peptides (APPs). Mucous membranes: in parallel with and induced by an increasingly complex microbiota, the newborn intestinal mucosal epithelium rapidly changes structurally, with an increase in the population of crypts and crypt-based Paneth cells, as well as functionally with increasing APP expression. Blood: the composition of neonatal blood is distinct, with relatively low concentrations of complement components and APPs and high concentrations of the immunosuppressive purine metabolite adenosine. Plasma also contains maternal antibodies that are transferred beginning midgestation and supplemented by postnatal factors derived from breast milk. Innate immunity is detectable from the end of the 1st mo of gestation, with changes driven largely by the increasing exposure to environmental microbes. Neonatal antigen-presenting cells such as blood monocytes express pattern recognition receptors (e.g., Toll-like receptors, TLRs) with distinct functional responses, including limited Th1-polarizing cytokine production, to most stimuli. Adaptive immunity develops from 4 wk of gestation onward, with changes driven by an evolving chimerism reflecting fetal (liver-derived, *shaded cells*) regulatory T (Treg)-cell–rich lymphocytes, and more adultlike (bone marrow derived, *unshaded cells*) lymphocytes with distinct, epigenetically encoded functional programs. Ig, Immunoglobulin; RBC, red blood cell. (Modified from Kollmann TR, Kampmann B, Mazmanian SK, et al: Protecting the newborn and young infant from infectious diseases: lessons from immune ontogeny. *Immunity* 2007;46:350–363.)

Incidence and Epidemiology

Despite advances in maternal and neonatal care, infections remain a frequent and important cause of neonatal and infant morbidity and mortality. Up to 10% of infants have infections in the 1st mo of life. Newborn infection is more common in areas with limited access to healthcare than in areas with well-established healthcare infrastructure. The overall incidence of neonatal sepsis ranges from 1 to 5 cases per 1,000 live births. Estimated incidence rates vary based on the case definition and the population studied. Globally, neonatal sepsis and other severe infections were responsible for an estimated 430,000 neonatal deaths in 2013, accounting for approximately 15% of all neonatal deaths.

A number of bacterial and nonbacterial agents may infect newborns in the intrapartum or postpartum period (Table 129.1). Although herpes simplex virus (HSV), human immunodeficiency virus (HIV), hepatitis B virus (HBV), hepatitis C virus (HCV), and tuberculosis (TB) can each result in transplacental infection, the most common mode of transmission for these agents is **intrapartum** , during labor and delivery with passage through an infected birth canal (HIV, HSV, HBV), or **postpartum** , from contact with an infected mother or caretaker (TB) or with infected breast milk (HIV) (Fig. 129.2 and Table 129.2). Any microorganism inhabiting the genitourinary or lower gastrointestinal tract may cause intrapartum and postpartum infection. The most common bacteria are group B streptococcus (GBS), *Escherichia coli,* and *Klebsiella* spp. *Salmonella* spp. are common causes of gram-negative sepsis in developing countries; less common causes of bacterial infection in the United States include *Citrobacter* , enterococci, gonococci, *Listeria monocytogenes* , *Streptococcus pneumoniae,* and *Haemophilus influenzae* . The more common viruses are cytomegalovirus (CMV), HSV, enteroviruses, and HIV (Table 129.2).

Legionella

* More likely with mechanical ventilation or indwelling catheters, or after abdominal surgery.

The most common bacterial causes of **neonatal meningitis** are GBS, *E. coli*, and *L. monocytogenes. S. pneumoniae*, other streptococci, nontypable *H. influenzae*, both coagulase-positive and coagulase-negative staphylococci, *Klebsiella*, *Enterobacter*, *Pseudomonas*, *Treponema pallidum*, and *Mycobacterium tuberculosis* infection involving the central nervous system (CNS) may also result in meningitis.

Early- and Late-Onset Neonatal Infections

The terms *early-onset infection* and *late-onset infection* refer to the different ages at onset of infection in the neonatal period. **Early-onset sepsis** is defined as the onset of symptoms before 7 days of age, although some experts limit the definition to infections occurring within the 1st 72 hr of life. **Late-onset sepsis** is generally defined as the onset of symptoms at ≥7 days of age. Similar to early-onset sepsis, there is variability in the definition, ranging from an onset at >72 hr of life to ≥7 days of age. Early-onset infections are acquired before or during delivery (**vertical** mother-to-child transmission). Late-onset infections develop after delivery from organisms acquired in the hospital or the community. The age at onset depends on the timing of exposure and virulence of the infecting organism. **Very-late-onset infections** (onset after age 1 mo) may also occur, particularly in very-low-birthweight (VLBW) preterm infants or term infants requiring prolonged neonatal intensive care.

The incidence of neonatal bacterial sepsis varies from 1-4 per 1,000 live births, with geographic variation and changes over time. Studies suggest that term male infants have a higher incidence of sepsis than term females. This sex difference is less clear in preterm low-birthweight (LBW) infants. Attack rates of neonatal sepsis increase significantly in LBW infants in the presence of maternal chorioamnionitis, congenital immune defects, mutations of genes involved in the innate immune system, asplenia, galactosemia *(E. coli)*, and malformations leading to high inocula of bacteria (e.g., obstructive uropathy).

Data from the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) Neonatal Research Network documented rates of early-onset sepsis among almost 400,000 live births at Network centers. The overall rate of early-onset sepsis was 0.98 cases per 1,000 live births, with rates inversely related to birthweight: 401-1,500 g, 10.96 per 1,000 births; 1,501-2,500 g, 1.38/1,000; and >2,500 g, 0.57/1,000 (Table 129.4).

Table 129.4

Rates of Early-Onset Sepsis Per 1,000 Live Births[*]

	BIRTHWEIGHT (g)			
	401-1,500	**1,501-2,500**	**>2,500**	**All**
All	10.96	1.38	0.57	0.98
Group B streptococci	2.08	0.38	0.35	0.41
Escherichia coli	5.09	0.54	0.07	0.28

[*] NICHD Neonatal Research Network/CDC Surveillance Study of Early-Onset Sepsis.

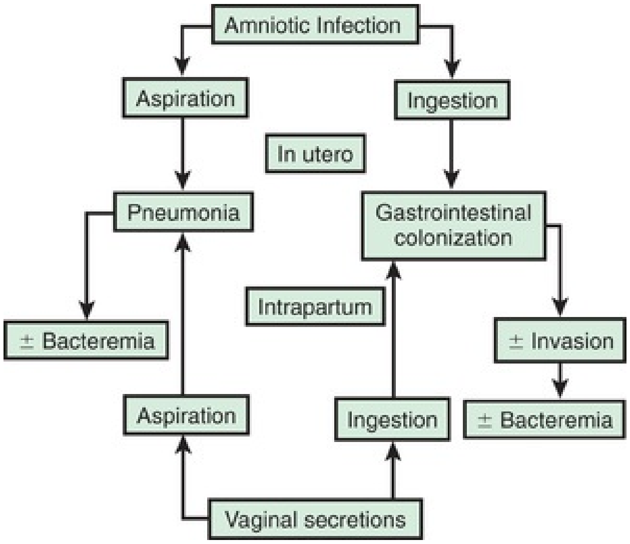
Adapted from Stoll BJ, Hansen NI, Sanchez PJ, et al: Early onset neonatal sepsis: the burden of group B streptococcal and *E. coli* disease continues, *Pediatrics* 127(5):817–826, 2011.

The incidence of meningitis is 0.2-0.4 per 1,000 live births in newborn infants and is higher in preterm infants. Bacterial meningitis may be associated with sepsis or may occur as a local meningeal infection. *Up to one third of VLBW infants with late-onset meningitis have negative blood culture results* . The discordance between results of blood and cerebrospinal fluid (CSF) cultures suggests that meningitis may be underdiagnosed among VLBW infants and emphasizes the need for culture of CSF in VLBW infants when *late-onset sepsis* is suspected and in all infants who have positive blood culture results. Most neonates with sepsis presenting in the 1st day of life have a positive blood culture; analysis of CSF is usually deferred until the unstable cardiorespiratory status (shock, respiratory failure) has stabilized.

Pathogenesis

Early-Onset Infections

In most cases, the fetus or neonate is not exposed to potentially pathogenic bacteria until the membranes rupture and the infant passes through the birth canal and/or enters the extrauterine environment. The human birth canal is colonized with aerobic and anaerobic organisms that may result in ascending amniotic infection and/or colonization of the neonate at birth. Vertical transmission of bacterial agents that infect the amniotic fluid and vaginal canal may occur in utero or, more often, during labor and delivery (Fig. 129.3).



Amniotic Infection

Vaginal secretions

FIG. 129.3 **Pathways of ascending or intrapartum infection.**

Chorioamnionitis results from microbial invasion of amniotic fluid, often as a result of prolonged rupture of the chorioamniotic membrane. Amniotic infection may also occur with apparently intact membranes or with a relatively brief duration of membrane rupture. The term *chorioamnionitis* refers to the clinical syndrome of intrauterine infection, which includes maternal fever, with or without local or systemic signs of chorioamnionitis (uterine tenderness, foul-smelling vaginal discharge/amniotic fluid, maternal leukocytosis, maternal and/or fetal tachycardia). Chorioamnionitis may also be asymptomatic, diagnosed only by amniotic fluid analysis or pathologic examination of the placenta. The rate of histologic chorioamnionitis is inversely related to gestational age at birth (Fig. 129.4) and directly related to duration of membrane rupture.

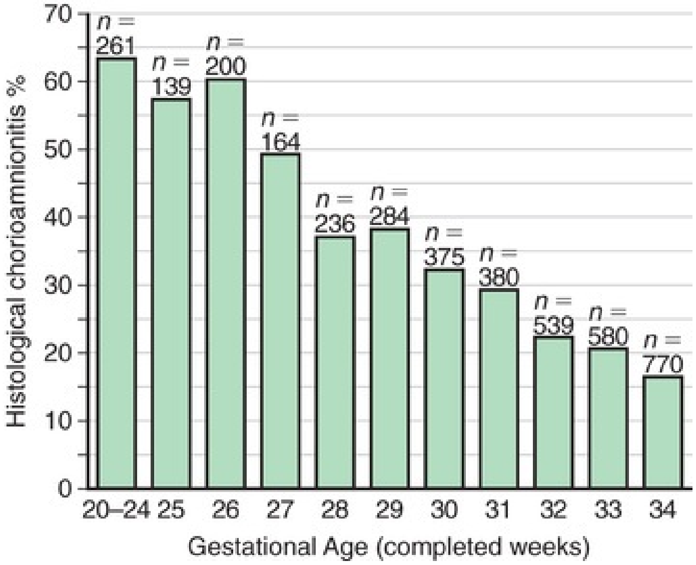

FIG. 129.4 **Histologic chorioamnionitis in liveborn preterm babies by gestational age (*n* = 3,928 babies). (From Lahra MM, Jeffery HE: A fetal response to chorioamnionitis is associated with early survival after preterm birth, *Am J Obstet Gynecol* 190:147–151, 2004.)**

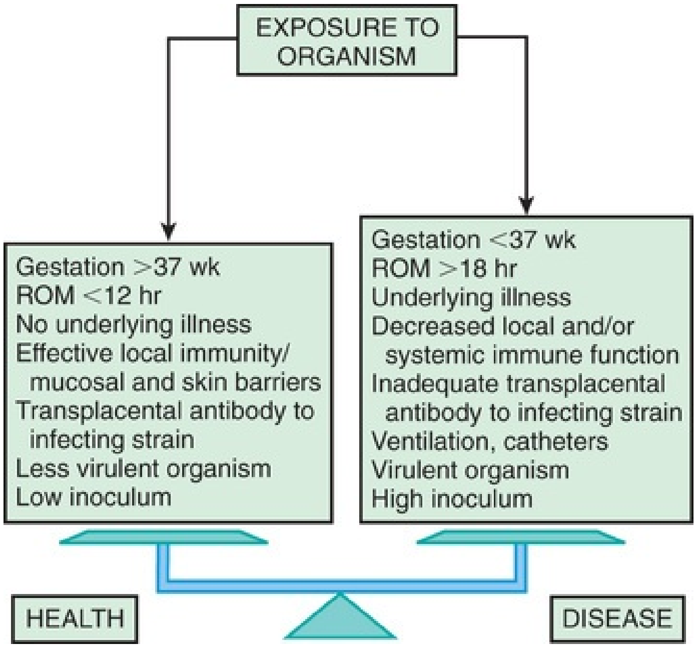
Chorioamnionitis was thought to result from infection of the amniotic fluid but is now better defined by the term **intrauterine inflammation or infection at birth (Triple I)** . This is defined by fetal tachycardia, maternal leukocytosis (>15,000 cells in the absence of corticosteroids), purulent fluid from the cervical os, biochemical or microbiologic amniotic fluid changes consistent with infection, and fever (≥39.0°C/10.2°F) (see Chapter 131.2).

Rupture of membranes for >24 hr was once considered prolonged because microscopic evidence of inflammation of the membranes is uniformly present when the duration of rupture exceeds 24 hr. At 18 hr of membrane rupture, however, the incidence of early-onset disease with group B streptococcus (GBS) increases significantly; 18 hr is the appropriate cutoff for increased risk of neonatal infection (see Chapter 211).

Bacterial colonization does not always result in disease. Factors influencing which colonized infant will experience disease are not well understood but include prematurity, underlying illness, invasive procedures, inoculum size, virulence of the infecting organism, genetic predisposition, the innate immune system, host response, and transplacental maternal antibodies (Fig. 129.5). Aspiration or ingestion of bacteria in amniotic fluid may lead to congenital pneumonia or systemic infection, with manifestations becoming apparent before delivery (fetal distress, tachycardia), at delivery (failure to breathe, respiratory distress, shock), or after a latent period of a few hours (respiratory distress, shock). Aspiration or ingestion of bacteria during the birth process may lead to infection after an interval of 1-2 days.



EXPOSURE TO ORGANISM
Gestation >37 wk
ROM <12 hr
No underlying illness
Effective local immunity/ mucosal and skin barriers
Transplacental antibody to infecting strain
Less virulent organism
Low inoculum
Gestation <37 wk
ROM >18 hr
Underlying illness
Decreased local and/or systemic immune function
Inadequate transplacental antibody to infecting strain
Ventilation, catheters
Virulent organism
High inoculum
HEALTH
DISEASE

FIG. 129.5 **Factors influencing the balance between health and disease in neonates exposed to a potential pathogen. ROM, Rupture of membranes. (Adapted from Baker CJ: Group B streptococcal infections, *Clin Perinatol* 24:59–70, 1997.)**

Resuscitation at birth, particularly if it involves endotracheal intubation, insertion of an umbilical vessel catheter, or both, is associated with an increased risk of bacterial infection. Explanations include the presence of infection at the time of birth or acquisition of infection during the invasive procedures associated with resuscitation.

Late-Onset Infections

After birth, neonates are exposed to infectious agents in the neonatal intensive care unit (NICU), the nursery, or in the community (including family). Postnatal infections may be transmitted by direct contact with hospital personnel, the mother, or other family members; from breast milk (HIV, CMV); or from inanimate sources such as contaminated equipment. The most common source of postnatal infections in hospitalized newborns is *hand contamination* of healthcare personnel, underscoring the importance of handwashing.

Most cases of meningitis result from hematogenous dissemination. Less often, meningitis results from contiguous spread as a result of contamination of open neural tube defects, congenital sinus tracts, or penetrating wounds from fetal scalp sampling or internal fetal electrocardiographic monitors. Cerebral abscess formation, ventriculitis, septic infarcts, hydrocephalus, and subdural effusions are complications of meningitis that occur more often in newborn infants than in older children. Metabolic factors, including hypoxia, acidosis, hypothermia, and inherited metabolic disorders (e.g., galactosemia), are likely to contribute to risk for and severity of neonatal sepsis

Infection in Premature Infants

The most important neonatal factor predisposing to infection is prematurity or LBW. Preterm LBW infants have a 3- to 10-fold higher incidence of infection than full-term normal-birthweight infants. Possible explanations include (1) maternal genital tract infection is considered to be an important cause of preterm labor, with an increased risk of vertical transmission to the newborn; (2) the frequency of intraamniotic infection is inversely related to gestational age (see Figs. 129.1 and 129.5); (3) premature infants have documented immune dysfunction; and (4) premature infants often require prolonged intravenous access, endotracheal intubation, or other invasive procedures that provide a portal of entry or impair barrier and clearance mechanisms, putting them at continued risk for hospital-acquired infections.

Clinical Manifestations

The maternal history provides important information about maternal exposures to infectious diseases, bacterial colonization, immunity (natural and acquired), and obstetric risk factors (prematurity, prolonged ruptured membranes, maternal chorioamnionitis). Signs and symptoms in the neonate are often subtle and nonspecific. Temperature instability, tachypnea, lethargy, and poor feeding are common initial signs and should raise suspicion for systemic or focal infection (Table 129.5).

Table 129.5

Initial Signs and Symptoms of Infection in Newborn Infants

GENERAL
Fever, temperature instability
“Not doing well”
Poor feeding
Edema
GASTROINTESTINAL SYSTEM
Abdominal distention

Bleeding

Bacterial Sepsis

Neonates with bacterial sepsis may have either nonspecific manifestations or focal signs of infection (Table 129.5), including temperature instability, hypotension, poor perfusion with pallor and mottled skin, metabolic acidosis, tachycardia or bradycardia, apnea, respiratory distress, grunting, cyanosis, irritability, lethargy, seizures, feeding intolerance, abdominal distention, jaundice, petechiae, purpura, and bleeding. Table 129.6 lists World Health Organization *international criteria* for bacterial sepsis. The initial manifestation may involve only limited symptomatology and only one system, such as apnea alone or tachypnea with retractions, or tachycardia, or the infant may present with an acute catastrophic manifestation with multiorgan dysfunction and shock. Infants should be reevaluated over time to determine whether the symptoms have progressed from mild to severe. Later complications of sepsis include respiratory failure, pulmonary hypertension, cardiac failure, shock, renal failure, liver dysfunction, cerebral edema or thrombosis, adrenal hemorrhage and/or insufficiency, bone marrow dysfunction (neutropenia, thrombocytopenia, anemia), and disseminated intravascular coagulopathy (DIC).

Table 129.6

Clinical Criteria for the Diagnosis of Sepsis in the International Setting

IMCI AND WHO CRITERIA FOR SEVERE INFECTIONS IN CHILDREN

Neurologic: convulsions, drowsy or unconscious, decreased activity, bulging fontanel
Respiratory: respiratory rate >60 breaths/min, grunting, severe chest indrawing, central cyanosis
Cardiac: poor perfusion, rapid and weak pulse
Gastrointestinal: jaundice, poor feeding, abdominal distention
Dermatologic: skin pustules, periumbilical erythema or purulence
Musculoskeletal: edema or erythema overlying bones or joints
Other: temperature >37.7°C (99.9°F; or feels hot) or <35.5°C (95.9°F; or feels cold)

IMCI, Integrated Management of Childhood Illness; WHO, World Health Organization.

Adapted from WHO: *Pocket book of hospital care for children: guidelines for the management of common childhood illnesses,* ed 2, Geneva, 2013, WHO, pp 45–69. http://www.who.int/maternal_child_adolescent/documents/child_hospital_care/en/ .

A variety of noninfectious conditions can occur together with neonatal infection or can make the diagnosis of infection more difficult. Respiratory distress syndrome (RDS) secondary to surfactant deficiency can coexist with bacterial pneumonia. Because bacterial sepsis can be rapidly progressive, the physician must be alert to the signs and symptoms of possible infection and must initiate diagnostic evaluation and empirical therapy in a timely manner. The differential diagnosis of many of the signs and symptoms that suggest infection is extensive; noninfectious disorders must also be considered (Table 129.7).

Table 129.7

Serious Systemic Illness in Newborns: Differential Diagnosis of Neonatal Sepsis

CARDIAC
Congenital: hypoplastic left heart syndrome, other structural disease, persistent pulmonary hypertension of the newborn (PPHN)
Acquired: myocarditis, hypovolemic or cardiogenic shock, PPHN
GASTROINTESTINAL
Necrotizing enterocolitis
Spontaneous gastrointestinal perforation
Midgut volvulus
Hepatic failure (inborn errors of metabolism, neonatal iron storage disease)
HEMATOLOGIC
Neonatal purpura fulminans
Immune-mediated thrombocytopenia
Immune-mediated neutropenia
Severe anemia
Malignancies (congenital leukemia)
Langerhans cell histiocytosis
Hereditary clotting disorders
Familial hemophagocytosis syndrome
METABOLIC
Hypoglycemia
Adrenal disorders: adrenal hemorrhage, adrenal insufficiency, congenital adrenal hyperplasia
Inborn errors of metabolism: organic acidurias, lactic acidoses, urea cycle disorders, galactosemia
NEUROLOGIC
Intracranial hemorrhage: spontaneous, caused by child abuse
Hypoxic-ischemic encephalopathy
Neonatal seizures
Infant botulism
RESPIRATORY
Respiratory distress syndrome
Aspiration pneumonia: amniotic fluid, meconium, or gastric contents
Lung hypoplasia
Tracheoesophageal fistula
Transient tachypnea of the newborn

Systemic Inflammatory Response Syndrome

The clinical manifestations of infection depend on the virulence of the infecting organism and the body's inflammatory response. The term *systemic inflammatory response syndrome* (SIRS) is most frequently used to describe this unique process of infection and the subsequent systemic response (see Chapters

88). In addition to infection, SIRS may result from trauma, hemorrhagic shock, other causes of ischemia, necrotizing enterocolitis, and pancreatitis.

Patients with SIRS have a spectrum of clinical symptoms that represent progressive stages of the pathologic process. In adults, SIRS is defined by the presence of 2 or more of the following: (1) fever or hypothermia, (2) tachycardia, (3) tachypnea, and (4) abnormal white blood cell (WBC) count or an increase in immature forms. In neonates and pediatric patients, SIRS manifests as temperature instability, respiratory dysfunction (altered gas exchange, hypoxemia, acute respiratory distress syndrome), cardiac dysfunction (tachycardia, delayed capillary refill, hypotension), and perfusion abnormalities (oliguria, metabolic acidosis) (Table 129.8). Increased vascular permeability results in capillary leak into peripheral tissues and the lungs, with resultant peripheral and pulmonary edema. DIC results in the more severely affected cases. The cascade of escalating tissue injury may lead to multisystem organ failure and death.

Table 129.8

Definitions of Systemic Inflammatory Respiratory Response Syndrome (SIRS) and Sepsis in Pediatric Patients

SIRS: the systemic inflammatory response to a variety of clinical insults, manifested by 2 or more of the following conditions:

- Temperature instability <35°C (95°F) or >38.5°C (101.3°F)
- Respiratory dysfunction:
  - Tachypnea >2 SD above the mean for age
  - Hypoxemia ($\mathrm{PaO_2}$ <70 mm Hg on room air)
- Cardiac dysfunction:
  - Tachycardia >2 SD above the mean for age
  - Delayed capillary refill >3 sec
  - Hypotension >2 SD below the mean for age
- Perfusion abnormalities:
  - Oliguria (urine output <0.5 mL/kg/hr)
  - Lactic acidosis (elevated plasma lactate and/or arterial pH <7.25)
  - Altered mental status

Sepsis: the systemic inflammatory response to an infectious process

From Adams-Chapman I, Stoll BJ: Systemic inflammatory response syndrome, *Semin Pediatr Infect Dis* 12:5–16, 2001.

Temperature Instability

Fever or hypothermia may be the only initial manifestation of serious infection in newborns. However, only approximately 50% of infected newborn infants have a temperature >37.8°C (100°F) (axillary) (see Chapter 202). Fever in newborn infants does not always signify infection; it may be caused by increased ambient temperature, isolette or radiant warmer malfunction, dehydration, CNS disorders, hyperthyroidism, familial dysautonomia, or ectodermal dysplasia. A single temperature elevation is infrequently associated with infection; fever sustained over 1 hr is more likely to be caused by infection. Most febrile infected infants have additional signs compatible with infection, although a focus of infection is not always apparent. Acute febrile illnesses occurring later in the neonatal period may be caused by urinary tract infection, meningitis, pneumonia, osteomyelitis, or gastroenteritis, in addition to sepsis, thus underscoring the importance of a diagnostic evaluation that includes blood culture, urine culture, lumbar puncture (LP), and other studies as indicated. Many agents may cause these late infections, including HSV, enteroviruses, respiratory syncytial virus (RSV), and bacterial pathogens. In premature infants, hypothermia or temperature instability requiring increasing ambient (isolette, warmer) temperatures is more likely to accompany infection.

Respiratory and Cardiovascular Symptoms

Early signs and symptoms of **pneumonia** may be nonspecific, including poor feeding, lethargy, irritability, cyanosis, temperature instability, and the overall impression that the infant is not well. Respiratory symptoms of increasing severity are grunting, tachypnea, retractions, flaring of the alae nasi, cyanosis, apnea, and progressive respiratory failure. If the infant is premature, signs of progressive respiratory distress may be superimposed on RDS or bronchopulmonary dysplasia (BPD). For infants on mechanical ventilation, the need to increase ventilator support may indicate infection. Although a common finding in neonatal sepsis, tachycardia is nonspecific. Bradycardia may also occur. Poor perfusion and hypotension are more sensitive indicators of sepsis but tend to be late findings. In a prospective national surveillance study, 40% of neonates with sepsis required volume expansion, and 29% required vasopressor support.

Signs of pneumonia on physical examination, such as dullness to percussion, change in breath sounds, and the presence of rales or rhonchi, are very difficult to appreciate in a neonate. Radiographs of the chest may reveal new infiltrates or an effusion, but if the neonate has underlying RDS or BPD, it is very difficult to determine whether the radiographic changes represent a new process or worsening of the underlying disease.

The progression of neonatal pneumonia can be variable. Fulminant infection is most frequently associated with pyogenic organisms such as GBS (see Chapter 211). Onset may occur during the 1st hours or days of life, with the infant often manifesting rapidly progressive circulatory collapse and respiratory failure. With early-onset pneumonia in premature infants, the clinical course and chest radiographs may be indistinguishable from those with severe RDS.

In contrast to the rapid progression of pneumonia caused by pyogenic organisms, an indolent course may be seen in nonbacterial infection. The onset can be preceded by upper respiratory tract symptoms or conjunctivitis. The infant may demonstrate a nonproductive cough, and the degree of respiratory compromise is variable. Fever is usually absent or low grade, and radiographic examination of the chest shows focal or diffuse interstitial pneumonitis or hyperinflation. Infection is generally caused by *C. trachomatis,* CMV, *Ureaplasma urealyticum,* or one of the respiratory viruses. Rhinovirus has been reported to cause severe respiratory compromise in infants, particularly those who are preterm. Although *Pneumocystis (carinii) jiroveci* was implicated in the past, its etiologic role is now in doubt, except in newborns infected with HIV.

Conjunctivitis

Conjunctival infection is relatively common and may be caused by a variety of organisms. The presentation includes periorbital swelling, conjunctival injection, and purulent conjunctival drainage. *C. trachomatis* and *Neisseria gonorrhea* are common causes; other gram-positive and gram-negative organisms are occasionally involved. *Pseudomonas aeruginosa* is an important pathogen in hospitalized VLBW infants and may be a precursor to invasive disease. Viral infections (e.g., HSV, adenovirus) are occasionally seen. Recognition of HSV infection is important to prevent corneal injury and dissemination to systemic sites.

Skin and Soft Tissue Infection

Cutaneous manifestations of infection include omphalitis, cellulitis, mastitis, and subcutaneous abscesses. Pustules likely indicate the presence of staphylococcal infection but must be distinguished from the vesicular rash of HSV infection. Staphylococcal pustulosis results in larger, pus-filled lesions 1 mm in diameter and often scattered around the umbilicus, whereas HSV infection often appears as tiny vesicles in crops, often on the scalp. **Ecthyma gangrenosum** indicates infection with *Pseudomonas* spp. and is rare except in VLBW infants. The presence of small, salmon-pink papules suggests *L. monocytogenes* infection. Mucocutaneous lesions suggest *Candida* spp. (see Chapter 261.1). Petechiae and purpura may be the result of systemic viral or bacterial infection.

Omphalitis

Omphalitis is a neonatal infection resulting from unhygienic care of the umbilical cord, which continues to be a problem, particularly in developing countries. The umbilical stump is colonized by bacteria from the maternal genital tract and the environment (see Chapter 125). The necrotic tissue of the umbilical cord is an excellent medium for bacterial growth. Omphalitis may remain a localized infection or may spread to the abdominal wall, the peritoneum, the umbilical or portal vessels, and the liver. Abdominal wall cellulitis or **necrotizing fasciitis** , with associated sepsis and a high mortality rate, may develop in infants with omphalitis. Prompt diagnosis and treatment are necessary to avoid serious complications. *Staphylococcus aureus* and gram-negative organisms are common pathogens involved.

Tetanus

Neonatal tetanus remains a serious infection in resource-limited countries (see Chapter 238). It results from unclean delivery and unhygienic management of the umbilical cord in an infant born to a mother who has not been immunized against tetanus. The surveillance case definition of neonatal tetanus requires the ability of a newborn to suck at birth and for the 1st few days of life, followed by an inability to suck. Neonatal tetanus typically occurs in infants 5-7 days after birth (range: 3-24 days), difficulty swallowing, spasms, stiffness, seizures, and death. **Bronchopneumonia** , presumably resulting from aspiration, is a common complication and cause of death. Neonatal tetanus can be prevented by immunizing mothers before or during pregnancy and by ensuring a clean delivery, sterile cutting of the umbilical cord and proper cord care after birth.

Laboratory Findings

Maternal history and infant signs should guide diagnostic evaluation (Table 129.9). Additionally, signs of systemic infection in newborn infants may be unrevealing, so laboratory investigation plays a particularly important role in diagnosis. Cultures and cell counts are obtained from blood and urine. CSF should be sent for Gram stain, routine culture, cell count with differential, and protein/glucose concentrations. Surface swabs, blood, and CSF are often obtained for HSV testing. Except for culture and directed pathogen testing, no single laboratory test is completely reliable for diagnosis of invasive infection in the newborn. Complete blood count may demonstrate elevated or decreased WBC count, often with a shift toward more immature forms. Thrombocytopenia can be seen in systemic bacterial or viral infection. Hyponatremia, acidosis, and other electrolyte abnormalities can be seen. Hyperbilirubinemia is nonspecific but may be an indication of systemic infection. Elevated serum transaminases may be a clue to systemic HSV or enterovirus infection.

Table 129.9

Evaluation of a Newborn for Infection or Sepsis

HISTORY (SPECIFIC RISK FACTORS)

- Maternal infection during gestation or at parturition (type and duration of antimicrobial therapy):
    - Urinary tract infection
    - Chorioamnionitis
- Maternal colonization with group B streptococci, *Neisseria gonorrhoeae* , herpes simplex
- Low gestational age/birthweight
- Multiple birth
- Duration of membrane rupture
- Complicated delivery
- Fetal tachycardia (distress)
- Age at onset (in utero, birth, early postnatal, late)
- Location at onset (hospital, community)
- Medical intervention:
    - Vascular access
    - Endotracheal intubation
    - Parenteral nutrition
    - Surgery

EVIDENCE OF OTHER DISEASES *

- Congenital malformations (heart disease, neural tube defect)
- Respiratory tract disease (respiratory distress syndrome, aspiration)
- Necrotizing enterocolitis
- Metabolic disease (e.g., galactosemia)

EVIDENCE OF FOCAL OR SYSTEMIC DISEASE

- General appearance, neurologic status
- Abnormal vital signs

Organ system disease
Feeding, stools, urine output, extremity movement
LABORATORY STUDIES
Evidence of Infection
Culture from a normally sterile site (blood, CSF, other)
Demonstration of a microorganism in tissue or fluid
Molecular detection (blood, urine, CSF) by specific PCR and/or 16S ribosomal DNA
Maternal or neonatal serology (syphilis, toxoplasmosis)
Evidence of Inflammation
Leukocytosis, increased immature/total neutrophil count ratio
Acute-phase reactants: C-reactive protein, erythrocyte sedimentation rate, procalcitonin
Cytokines: interleukin-6, interleukin-B, tumor necrosis factor
Pleocytosis in CSF or synovial or pleural fluid
Disseminated intravascular coagulation: fibrin degradation products, D-dimer
Evidence of Multiorgan System Disease
Metabolic acidosis: pH, P_{CO_2}
Pulmonary function: P_{O_2}, P_{CO_2}
Renal function: blood urea nitrogen, creatinine
Hepatic injury/function: bilirubin, alanine transaminase, aspartate transaminase, ammonia, prothrombin time, partial thromboplastin time
Bone marrow function: neutropenia, anemia, thrombocytopenia

[*] Diseases that increase the risk of infection or may overlap with signs of sepsis.

CSF, Cerebrospinal fluid; PCR, polymerase chain reaction.

Various serum biomarkers have been investigated for their ability to identify infants with **serious bacterial infection** (SBI). An immature-to-total phagocyte count (I/T ratio) (≥0.2) has the best sensitivity of the neutrophil indices for predicting neonatal sepsis. After the newborn period, serum C-reactive protein (CRP) and procalcitonin have demonstrated reasonable sensitivity and specificity for SBI. CRP may be monitored in newborn infants to assess response to therapy. Their value in the initial diagnosis of sepsis in the newborn period has yet to be clarified, as does the value of these biomarkers in determining optimal length of empirical therapy in infants with negative cultures. Cytokines (both proinflammatory cytokines such as interleukin (IL)-6 and tumor necrosis factor-α and antiinflammatory cytokines such as IL-4 and IL-10), chemokines, and other biomarkers are increased in infected infants. Elevations of serum amyloid A and the cell surface antigen CD64 also have high sensitivity for identifying infants with sepsis. Chest radiography is generally not indicated in infants without signs of respiratory infection.

Table 129.9 and 129.10 list clinical features and laboratory parameters that are useful in the diagnosis of neonatal infection or sepsis.

Table 129.10

Culture-Based and Non–Culture-Based Diagnostics for

Neonatal Sepsis

CATEGORY	PARAMETER	OPTIMAL TIMING, VOLUME OF SPECIMEN, ROUTINE/INVESTIGATIONAL*	APPLICABILITY FOR NEONATAL SEPSIS
CULTURE BASED			
Blood	Culture	>1 mL of whole blood, from 2 sites	Gold standard for bacteremia
CSF	Culture	When clinically feasible	Optimize antimicrobial therapy
Urine	Culture	>72 hr of life	Not useful for EOS; potential benefits for LOS
Tracheal aspirate	Culture	Neonates with endotracheal tube in place and signs of progressive respiratory distress	Usually reflects colonization
NON–CULTURE BASED			
Immune function	MHC II TNF-α	Investigational Investigational	Both decreased in chorioamnionitis and sepsis
Neutrophil indices	Neutropenia Absolute neutrophil count Absolute immature neutrophil count	After 12 hr of life Consider GA, delivery mode, altitude, arterial versus venous sampling, time since birth	Neutropenia better predictor for sepsis than leukocytosis
Neutrophil markers	CD64	Elevated for 24 hr after infection Requires 50 µL blood Results within hours Investigational	Cut points between 2.38 and 3.62 optimal sensitivity, specificity, and NPV for EOS
Platelet count	Thrombocytopenia and thrombocytosis	Late findings; slow to respond	Thrombocytopenia associated with fungal infection
CSF cell count	CSF WBC	Uninfected neonates: mean 10 cells/mm^3 ; range up to 20 cells/mm^3	Does not predict culture-proven meningitis
CSF chemistries	CSF protein CSF glucose	Term <100 mg/dL Preterm higher; 70–80% of serum glucose	Elevated in fungal meningitis Low glucose specific for bacterial meningitis
Acute phase reactants	CRP Procalcitonin	8–24 hr after infection 2–12 hr after infection	Good NPV Better sensitivity but less specificity than CRP
Sepsis panels/scores		After 24 hr of life Investigational	Most useful for NPV and discontinuation of antimicrobial therapy

[*] *Investigational* refers to an assay or parameter that is undergoing evaluation for clinical use and applicability.

CRP, C-reactive protein; CSF, cerebrospinal fluid; EOS, early-onset sepsis; GA, gestational age; LOS, late-onset sepsis; MHC II, major histocompatibility complex class II; NPV, negative predictive value; TNF, tumor necrosis factor; WBC, white blood cell count.

From Shane AL, Stoll BJ. Recent developments and current issues in the epidemiology, diagnosis, and management of bacterial and fungal neonatal sepsis, *Am J Perinatol* 30(2):131–141, 2013.

General Approach to Management

In the absence of specific signs of focal infection, therapy for presumed infection in the neonate is often empirical and initiated on the basis of fever or hypothermia, listlessness, irritability, or apneic episodes. Antibiotics are chosen to cover the organisms typically causing neonatal sepsis, including GBS, gram-negative organisms, *Listeria* , and *Enterococcus* . Since the latter 2 organisms are intrinsically resistant to cephalosporins, ampicillin is generally included in the empirical treatment of infants with presumed neonatal infection (Table 129.11).

Table 129.11

Management and Prevention of Neonatal Sepsis

CONDITION	**THERAPY**	**ADDITIONAL CONSIDERATIONS**
EMPIRICAL MANAGEMENT		
Early-onset sepsis	Ampicillin + aminoglycoside 10 days for bacteremia; 14 days for GBS and uncomplicated meningitis; extend to 21-28 days for complicated infections	Consider a third-generation cephalosporin (cefotaxime preferred) or carbapenem for meningitis. Tailor therapy to pathogen. Consider discontinuation of therapy if pathogen not isolated.
Late-onset sepsis	Vancomycin + aminoglycoside Duration dependent on pathogen and site	Alternatives to vancomycin may be considered based on local epidemiology and clinical presentation. Aminoglycoside-based regimen preferred to cephalosporin given reduced risk of resistance. Consider cephalosporin if meningitis suspected. Consider a carbapenem if third-generation cephalosporin recently received. Consider amphotericin for fungal etiologies. Tailor therapy to pathogen. Consider discontinuation of therapy if pathogen not isolated.
NONANTIMICROBIAL TREATMENT STRATEGIES		
Recombinant G-CSF Recombinant GM-CSF	Enhance neutrophil number and function, but no reduction in infection when administered as prophylaxis or improvement in survival when administered as therapy.	Insufficient evidence to support the clinical use of G-CSF or GM-CSF either as treatment or prophylaxis to prevent systemic infections.
IVIG	Augments antibody-dependent cytotoxicity and improves neutrophilic function, *but* no evidence that IVIG in suspected or proven sepsis reduces death.	Insufficient evidence from 10 RCTs or quasi-RCTs to support use in neonates with confirmed or suspected sepsis.
PREVENTION STRATEGIES		

IAP	Administration of penicillin or ampicillin 4 hr before parturition	Successfully reduces rates of EOS caused by GBS No effect on LOS GBS
Fluconazole prophylaxis	Administration of weight-based dosing to neonates <1,500 g	Most beneficial in NICUs with high baseline rates of invasive candidiasis
BLF supplementation with a probiotic, *Lactobacillus rhamnosus* (GG)	BLF is a human milk glycoprotein with a role in innate immune response. LGG enhances the activity of lactoferrin.	BLF supplementation with and without LGG reduced the incidence of 1st LOS in 472 VLBW neonates in large randomized, double-blind RCT. Additional confirmatory studies warranted.

BLF, Bovine lactoferrin supplementation; EOS, early-onset sepsis; GBS, group B streptococcus; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IAP, intrapartum antimicrobial prophylaxis; IVIG, intravenous immune globulin, LGG, *Lactobacillus rhamnosus* GG; LOS, late-onset sepsis; NICUs, neonatal intensive care units; RCTs, randomized controlled trials; VLBW, very-low-birthweight.

Created with data from Carr R, Modi N, Doré C: G-CSF and GM-CSF for treating or preventing neonatal infections, *Cochrane Database Syst Rev* (3):CD003066, 2003; Brocklehurst P, Farrell B, King A, et al; INIS Collaborative Group: Treatment of neonatal sepsis with intravenous immune globulin, *N Engl J Med* 365:1201–1211, 2011; and Manzoni P, Decembrino L, Stolfi I, et al; Italian Task Force for the Study and Prevention of Neonatal Fungal Infections; Italian Society of Neonatology: Lactoferrin and prevention of late-onset sepsis in the pre-term neonates, *Early Hum Dev* 86(Suppl 1):59–61, 2010.

Used with permission from Shane AL, Stoll BJ. Recent developments and current issues in the epidemiology, diagnosis, and management of bacterial and fungal neonatal sepsis. *Am J Perinatol* 30(2):131–141, 2013.

An empirical regimen for suspected early-onset sepsis in a term or late preterm infant is **ampicillin** , 150 mg/kg/dose intravenously (IV) every 12 hr, and **gentamicin** , 4 mg/kg/dose IV every 24 hr. This has long been a standard regimen for early-onset sepsis and provides coverage for the most prevalent organisms, predominantly GBS and gram-negative ones. Ampicillin plus **cefotaxime** (if available) or **cefepime** may be substituted if the patient presents with infection after discharge from the nursery, or when infection with ampicillin-resistant *E. coli* is suspected. **Ceftriaxone** may be substituted if premature infants are ≥41 wk postconception age; it may be used in term infants if they are not receiving intravenous calcium or do not have hyperbilirubinemia. There is concern this regimen may be associated with higher rates of mortality in NICU patients compared to ampicillin and gentamicin. Alterations to the standard regimen may be appropriate in some circumstances, such as suspected infection with *S. aureus* , in which case **vancomycin** may be substituted for ampicillin, and in environments where infections from antibiotic-resistant bacteria are prevalent.

Herpes simplex virus infection may present without cutaneous signs, in the absence of maternal history of infection, and in mothers receiving suppressive antiviral therapy. Therefore, management of the ill newborn requires a high index of suspicion for HSV infection. Surface swabs, blood, and CSF are obtained for HSV culture or PCR, and empirical acyclovir is often recommended while the results of these studies are pending (see Chapters 202 and 279).

Systemic infection caused by *Candida* spp. is a concern in hospitalized infants, particularly VLBW infants with central venous access catheters and prior antibiotic use. Empirical therapy for fungal infection is generally not recommended unless the patient fails to respond to broad-spectrum antibiotic therapy.

Definitive therapy is based on identification and susceptibility of the offending organism. In almost all circumstances, the *leas* t *broad* antibiotic with activity against the organism is chosen. Duration of therapy depends on the organism and the site of infection. In neonates with culture-proven sepsis, the usual course of therapy is 10 days. Longer treatment courses may be warranted if a specific focus of infection is identified (e.g., meningitis, osteomyelitis, septic arthritis). Antimicrobial therapy should be altered based on the susceptibility profile of the pathogen isolated. In infants with a negative blood culture but a clinical status that remains concerning for a systemic infection, antibiotic therapy can be extended for as long as a total of 5 to 10 days. Sepsis is unlikely in these infants if they remain well and the blood culture is sterile at 48 hr. Empirical antibiotic therapy should be discontinued after 48 hr in these neonates.

Prevention

Intrapartum antibiotics are used to reduce vertical transmission of GBS (Table 129.12), as well as to lessen neonatal morbidity associated with preterm labor and preterm premature rupture of membranes (see Figs. 211.2 and 211.3 in Chapter 211). With introduction of selective intrapartum antibiotic prophylaxis to prevent perinatal transmission of GBS, rates of early-onset neonatal GBS infection in the United States declined from 1.7/1,000 live births to 0.25/1,000. Intrapartum chemoprophylaxis does *not* reduce the rates of late-onset GBS disease and has no effect on the rates of infection with non-GBS pathogens (see Chapter 211). Of concern is a possible increase in gram-negative infections (especially *E. coli*) in VLBW and possibly term infants despite a reduction in early GBS sepsis by intrapartum antibiotics.

Table 129.12

Indications for Intrapartum Antibiotic Prophylaxis to Prevent Early-Onset GBS Disease

INTRAPARTUM GBS PROPHYLAXIS INDICATED	INTRAPARTUM GBS PROPHYLAXIS NOT INDICATED
Previous infant with invasive GBS disease	Colonization with GBS during a previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy)
GBS bacteriuria during any trimester of the current pregnancy	GBS bacteriuria during previous pregnancy (unless another indication for GBS prophylaxis is present for current pregnancy)
Positive GBS screening culture during current pregnancy (unless a cesarean delivery is performed before onset of labor or amniotic membrane rupture)	Cesarean delivery before onset of labor or amniotic membrane rupture, regardless of GBS colonization status or gestational age
Unknown GBS status at the onset of labor (culture not done, incomplete, or results unknown) and any of the following: Delivery at <37 weeks' gestation* Amniotic membrane rupture ≥18 hr Intrapartum temperature ≥38.0°C (100.4°F) † Intrapartum NAAT ‡ positive for GBS	Negative vaginal and rectal GBS screening culture in late gestation during the current pregnancy, regardless of intrapartum risk factors

* Recommendations for the use of intrapartum antibiotics for prevention of early-onset GBS disease in the setting of threatened preterm delivery are presented in Chapter 211 .

† If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.

‡ If intrapartum NAAT is negative for GBS but any other intrapartum risk factor (delivery at <37 wk gestation, amniotic membrane rupture ≥18 hr, or temperature ≥38.0°C/100.4°F) is present, intrapartum antibiotic prophylaxis is indicated.

GBS, Group B streptococcus; NAAT, nucleic acid amplification test.

From Verani J, McGee L, Schrag S: Prevention of perinatal group B streptococcal disease—revised guidelines from CDC, 2010, *MMWR Recomm Rep* 59(RR-10):1–36, 2010.

Aggressive management of suspected maternal chorioamnionitis with antibiotic therapy during labor, along with rapid delivery of the infant, reduces the risk of early-onset neonatal sepsis. Vertical transmission of GBS and early-onset GBS disease is significantly reduced by selective intrapartum chemoprophylaxis (see Fig. 211.4). A number of candidate GBS vaccines are currently being studied. Neonatal infection with *Chlamydia* can be prevented by identification and treatment of infected pregnant women (see Chapter 253). Mother-to-child transmission of HIV is significantly reduced by maternal antiretroviral therapy during pregnancy, labor, and delivery, by cesarean delivery before rupture of membranes, and by antiretroviral treatment of the infant after birth (see Chapter 302).

Prevention of congenital and perinatal infections predominantly focuses on maternal health. The Centers for Disease Control and Prevention (CDC) recommends the following screening tests and treatment when indicated:

1. All pregnant women should be offered voluntary and confidential HIV testing at the first prenatal visit, as early in pregnancy as possible. HIV screening should be part of routine prenatal testing, unless the mother declines testing (opt-out screening). For women at high risk of infection during pregnancy (multiple sexual partners or STIs during pregnancy, intravenous drug use, HIV-infected partners), repeat testing in the third trimester is recommended. Rapid HIV screening is indicated for any women who presents in labor with an undocumented HIV status, unless she declines testing.
2. A serologic test for syphilis should be performed on all pregnant women at the first prenatal visit. Repeat screenings early in the third trimester and again at delivery are recommended for women in whom syphilis test results in the first trimester were positive and for those at high risk for infection during pregnancy. Infants should not be discharged from the hospital unless the syphilis status of the mother has been determined at least once during pregnancy and preferably again at delivery.
3. Serologic testing for hepatitis B surface antigen (HBsAg) should be performed at the first prenatal visit, even if the woman has been previously vaccinated or tested. Women who were not screened prenatally, those who are at high risk for infection (multiple sexual partners, intravenous drug use, HBsAg-positive sex partner) and those with clinical hepatitis should be retested at the time of delivery.
4. A maternal genital culture for *C. trachomatis* should be performed at the first prenatal visit. Young women (<25 yr) and those at increased risk for infection (new or multiple partners during pregnancy) should be retested during the third trimester.
5. A maternal culture for *Neisseria gonorrhoeae* should be performed at the first prenatal visit. Those at high risk for infection should be retested in the third trimester.
6. All pregnant women at high risk for hepatitis C infection (intravenous drug use, blood transfusion or organ transplantation before 1992) should be screened for hepatitis C antibodies at the first prenatal visit.

7. Evidence does not support routine testing for bacterial vaginosis in pregnancy. For asymptomatic women at high risk for preterm delivery, testing may be considered. Symptomatic women should be tested and treated.
8. The CDC recommends universal screening for rectovaginal GBS colonization of all pregnant women at 35-37 wk gestation, and a screening-based approach to selective intrapartum antibiotic prophylaxis against GBS (Table 129.12) (see Figs. 211.2 and 211.3). Fig. 211.4 shows the approach to the infant born after intrapartum prophylaxis (see Chapter 211).

CHAPTER 130

Healthcare-Acquired Infections

David B. Haslam

Premature and very-low-birthweight (VLBW) infants often have prolonged hospitalizations and are particularly prone to healthcare-acquired infection (**HAI**) because of their inefficient innate immunity, deficient skin barriers, presence of indwelling catheters and other devices, and prolonged endotracheal intubation (Table 130.1). HAIs are associated with increased length of hospitalization, increased cost of care, and significant morbidity and mortality.

Table 130.1

Definitions of Healthcare-Acquired Infections for Patients <12 Mo Old*

NOSOCOMIAL BLOODSTREAM INFECTIONS
Laboratory-Confirmed Bloodstream Infection (LCBI)
Must meet 1 of the following definitions:
• Recognized pathogen in 1 or more blood specimens (culture-based or non–culture-based microbiologic methods), performed for clinical diagnostic or therapeutic purposes *and* not related to infection at another site.
• Commensal organism (e.g., coagulase-negative staphylococci, diphtheroids, bacillus, viridans streptococci, aerococcus, micrococcus, propionibacterium), identified from 2 or more blood specimens obtained on separate instances (culture- or non–culture-based microbiologic methods), performed for clinical diagnostic or therapeutic purposes *and* not related to infection at another site *and* at least 1 of the following signs: (1) fever (temperature >38.0°C), (2) hypothermia (temperature <36.0°C), or (3) apnea or bradycardia.
Central Line–Associated Bloodstream Infection (CLABSI)
• LCBI (as defined above) *and*
• Central line or umbilical catheter in place for >2 days *and*
• Central line in place on day of or day before CLABSI diagnosis.
Pneumonia
• Two or more serial chest radiographs with new/progressive and persistent infiltrate, cavitation, consolidation, or pneumatoceles for patients with underlying pulmonary or cardiac disease (respiratory distress syndrome, bronchopulmonary dysplasia, pulmonary edema) *or* 1 chest radiograph with the aforementioned abnormalities for patients without underlying pulmonary or cardiac disease *and*
• Worsening gas exchange *and*
• At least 3 of the following; (1) temperature instability; (2) white blood cell count <4,000/μL or >15,000/μL with

10% or more bands, (3) new-onset purulent sputum, change in character of sputum, increased respiratory secretions, or increased suctioning requirements; (4) physical examination findings consistent with increased work of breathing or apnea, wheezing, rales, or rhonchi; (5) cough; (6) bradycardia (<100 beats/min), and (7) tachycardia (>170 beats/min).
Ventilator-Associated Pneumonia (VAP)
• Pneumonia (as defined above) *and*
• Patient on ventilator for >2 days *and*
• Ventilator in place on day of or day before VAP diagnosis
URINARY TRACT INFECTION
Symptomatic Urinary Tract Infection (SUTI)
• At least 1 of the following symptoms: (1) fever (temperature >38.0°C), (2) hypothermia (temperature <36.0°C), (3) apnea, (4) bradycardia, (5) lethargy, (6) vomiting, or (7) suprapubic tenderness *and*
• Urine culture with no more than 2 species identified, at least 1 of which is present at $>10^5$ CFU/mL.
Asymptomatic Bacteremic Urinary Tract Infection (ABUTI)
• Urine culture with no more than 2 species identified, at least 1 of which is present at $>10^5$ CFU/mL *and*
• Bacteria identified in blood (culture-based or nonculture-based microbiologic method) that matches at least one of the bacteria present at more than 10^5 CFU/mL in urine.
Catheter–Associated Urinary Tract Infection:
• Urinary tract infection (as defined above, either SUTI or ABUTI) *and*
• Indwelling urinary catheter for >2 days *and*
• Urinary catheter in place on day of or day before urinary tract infection diagnosis.

Incidence

The most common HAIs in the neonatal intensive care unit (NICU) are bloodstream infections, predominantly central line–associated bloodstream infections. Ventilator-associated pneumonia (VAP) is the next most common, followed by surgical site infection and catheter-associated urinary tract infection.

Approximately 11% of NICU patients develop nosocomial infection during their hospitalization; up to 25% of VLBW infants will have blood culture–proven sepsis during their hospitalization. Infection rates are highest among the most premature infants. Ventilator-associated pneumonia accounts for approximately 25% of HAIs.

Epidemiology

HAIs in the NICU are predominantly caused by gram-positive organisms. The largest fraction of **bloodstream infections (BSIs)** in the NICU are caused by coagulase-negative staphylococci (Table 130.2). Other agents that often cause HAIs in the newborn include *Staphylococcus aureus*, enterococci, gram-negative bacilli *(Escherichia coli, Klebsiella pneumoniae, Enterobacter* spp., *Pseudomonas aeruginosa*), and *Candida.* Viruses contributing to HAIs in the neonate include rotavirus, enteroviruses, hepatitis A virus (HAV), adenoviruses, influenza, respiratory syncytial virus (RSV), rhinovirus, parainfluenza, and herpes simplex virus (HSV).

Table 130.2

Distribution of Organisms Responsible for Late-Onset Sepsis

ORGANISM	VLBW INFANTS: NICHD NRN (%)		
	1991–1993	1998–2000	2002–2008

Data from (1) 1991–1993: Stoll BJ, Gordon T, Korones SB, et al: Late-onset sepsis in very low birth weight neonates: a report from the NICHD NRN, *J Pediatr* 129:63–71, 1996; (2) 1998–2000: Stoll BJ, Hansen N, Fanaroff AA, et al: Late-onset sepsis in very low birth weight neonates: the experience of the NICHD NRN, *Pediatrics* 110:285–291, 2002; (3) 2002–2008: Boghossian NS, Page GP, Bell EF, et al: Late-onset sepsis in very low birth weight infants from singleton and multiple gestation births, J Pediatr 162:1120–1120, 2015.

Adapted from Ramasethu J. Prevention and treatment of neonatal nosocomial infections, *Matern Health Neonatol Perinatol* 3(5), 2017.

Bacteria responsible for most cases of nosocomial **pneumonia** typically include staphylococcal species, gram-negative enteric aerobes, and occasionally, *P. aeruginosa*. Fungi are responsible for an increasing number of systemic infections, usually acquired during prolonged hospitalization of preterm neonates. Respiratory viruses cause isolated cases and outbreaks of nosocomial pneumonia. These viruses, usually endemic during the winter months and acquired from infected hospital staff or visitors to the nursery, include RSV, parainfluenza virus, influenza viruses, and adenovirus.

Pathogenesis

Colonization of the skin, oropharynx, or gastrointestinal (GI) tract is an important precursor to infection in hospitalized infants. Premature infants may first be exposed to pathogenic organisms from a parent or more frequently from the hospital environment. Hospitalized infants are more likely to be colonized with *Staphylococcus aureus* , pathogenic gram-negative bacteria, and *Candida* than are infants in the community setting. Antibiotic exposure, indwelling devices, and frequent contact with contaminated medical equipment or healthcare providers all likely contribute to high rates of pathogen colonization. Following colonization, organisms may gain access to the bloodstream directly through damaged skin or central venous catheters. Recent evidence suggests the intestine is an important reservoir for invasive organisms, which may transit directly from the gut to the bloodstream. Oropharyngeal colonization with subsequent aspiration into the lower respiratory tract is thought to be the major route of infection in infants with ventilator-associated pneumonia.

Gestational age and birthweight are the most important risk factors for HAI. Prolonged use of central venous or umbilical catheters, exposure to broad-spectrum antibiotics, parenteral nutrition, and high nurse-to-patient ratios are other documented risk factors. These factors may alter the patient's endogenous microbial community, placing the infant at risk for colonization with pathogenic organisms.

Types of Infection

Central Line–Associated Bloodstream Infection

Central venous catheters have become an essential component of the care of critically ill newborns. Presence of a percutaneous or umbilical catheter introduces risk for infection and thrombosis. Central line–associated bloodstream infection (**CLABSI**) is the most common HAI in NICUs, imposing significant burden on the affected infant and on healthcare systems. Each episode has an attributable mortality of 4–20%. Infants with CLABSI subsequently have increased requirement for NICU stay, mechanical ventilation, and increased rates of bronchopulmonary dysplasia and necrotizing enterocolitis. The median estimated additional cost per CLABSI episode is $42,609, and hospitalization is prolonged for a median of 24 days.

Coagulase-negative staphylococci (CoNS) are the most common cause of CLABSI, accounting for approximately half of cases. CoNS are much more likely to cause clinically evident sepsis in VLBW infants than in term infants of comparable postnatal age, despite the organism's low pathogenic potential. Isolation of the organism from blood culture may represent contamination from the infant's or healthcare worker's skin, and blood cultures should be obtained from both peripheral and central venous sites. If both yield CoNS, the likelihood of true infection is high, whereas a single positive is considered questionable. In practice, often a single culture is obtained, and antibiotics are initiated before availability of a 2nd culture. In this circumstance, clinical judgment is often used to assess the need for targeted therapy. *S. aureus* , *Enterococcus* spp., and gram-negative rods account for most of the remaining CLABSIs during the 1st mo of hospitalization. Thereafter, *Candida* spp. become more prevalent, caused at least in part by their enrichment after broad-spectrum antibiotic exposure.

CLABSIs are generally thought to result from contamination of the central venous catheter, predominantly at the connecting hub or the skin entry site. An association has been shown between density of hub colonization and risk for CLABSI. Prevention of CLABSI is aimed at reducing contamination of these sites. BSI may also result from direct transit from the GI tract or other cutaneous or mucosal surfaces, analogous to recently defined **mucosal barrier injury–associated** BSIs. The contribution of mucosal sites to direct invasive infection remains to be clarified but has implications for infection prevention.

Healthcare-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is overall the 2nd most common HAI in neonatal units, although reported VAP rates vary widely (0.2-1.6 per 1,000 ventilator days). There is also variability in diagnosis of VAP, which consists of clinical, radiographic, and laboratory criteria, some of which are subjective or may be seen in noninfectious circumstances. The National Healthcare Safety Network and Centers for Disease Control and Prevention (CDC) definition of VAP requires at least 48 hr of mechanical ventilation accompanied by new and persistent radiographic infiltrates after the initiation of mechanical ventilation. In addition to these criteria, infants <1 yr old must exhibit worsening gas exchange and at least 3 of the following: (1) temperature instability with no other recognized cause; (2) leukopenia (white blood cell count <4,000/mm^3); (3) change in the character of sputum of increased respiratory secretions or suctioning requirements; (4) apnea, tachypnea, nasal flaring, or grunting; (5) wheezing, rales, rhonchi, or cough; or (6) bradycardia (<100 beats/min) or tachycardia (>170 beats/min). In practice, the diagnosis is often made on the basis of increased need for supplemental oxygen or new infiltrates on chest radiograph; either of which may be caused by factors other than infection. Further complicating the diagnosis of VAP, secretions aspirated from the airways of mechanically ventilated children often yield multiple organisms in culture, whether or not they have signs of infection. The most commonly reported organisms associated with VAP are gram-negative rods (including *Pseudomonas*), *S. aureus* , and *Enterococcus* . The source of infecting organisms is generally thought to be the infant's oropharynx, although contaminated respiratory equipment and tracheal suction catheters are occasionally implicated.

Skin and Soft Tissue Infection

Cutaneous infections are relatively common among hospitalized premature infants. Simple abrasions of frail skin, frequent vascular access, and surgical procedures predispose the skin to infection. *Staphylococcus aureus* is the most frequently isolated organism. **Methicillin-susceptible *S. aureus* (MSSA)** predominates despite increases in **methicillin-resistant *S. aureus* (MRSA)** infection rates during the last 2 decades. Gram-negative organisms and *Candida* spp. may occasionally be seen, particularly after intraabdominal surgery.

Invasive Fungal Infection

Up to 3% of VLBW and 20% of extremely-low-birthweight (ELBW) infants will develop invasive fungal infection, with a cumulative incidence of 1–4% of all

NICU admissions (see Chapter 261.1). Colonization, a requisite for subsequent infection is common after the 1st wk of hospitalization and is seen in >60% of infants at 1 mo in the NICU. *Candida albicans* accounts for most cases of colonization and infection, although *C. parapsilosis* and *C. glabrata* are prevalent in some NICUs. As with other BSIs, invasive candidiasis is often central venous catheter associated. In addition to gestational age and birthweight, risk factors include exposure to ≥2 antibiotics, receipt of H_2 blockers, parenteral nutrition (especially use of lipid emulsifiers), lack of enteral feeding, and GI surgery. Invasive candidiasis is associated with greater morbidity and mortality than invasive bacterial infection, with mortality rates >20% and long term developmental abnormalities seen in >50% of surviving infants.

Viral Infection

Nosocomially acquired viral infections receive less attention than invasive bacterial or fungal infections but can account for significant morbidity. Approximately 10% of reported episodes in NICUs are caused by viruses. The most common viral agent is **rotavirus** , followed by RSV, enterovirus, HAV, adenovirus, and influenza. Consistent with the viral etiology, GI illness is the most frequently reported virus-associated condition. In most cases of viral infection in the NICU, the source cannot be identified, making it difficult to focus preventive efforts. Response to viral outbreaks in the NICU can include enhanced patient surveillance, patient cohorting, and occasionally, closure of the affected patient care area.

Prevention

Hand Hygiene

Hand hygiene is the single most important intervention proven to prevent nosocomial infections, whereas *lack* of hand hygiene is one of the strongest correlates of HAI. Colonization with pathogenic organisms is known to increase with longer time spent performing patient interactions. The CDC and the World Health Organization have published guidelines on timing and choice of sanitizing agent during patient care (Table 130.3). Alcohol-based hand sanitizers are at least as effective as chlorhexidine-containing soaps in decreasing bacterial burden but have poor activity against certain important pathogens, including

Clostridium difficile , HAV, rotavirus, enterovirus, and adenovirus. Time constraints and workload are considered important barriers to adequate hand care, and recent evidence suggests that shortening the application time of alcohol-based sanitizers to 15 sec may improve frequency of use without impacting antimicrobial efficacy. Observational studies suggest that monitoring with personal or group-level feedback is among the most effective means to improve hand hygiene compliance.

Table 130.3

U.S. Centers for Disease Control and Prevention (CDC) Guidelines for Hand Hygiene

• When hands are visibly dirty or contaminated with proteinaceous material or are visibly soiled with blood or other body fluids, wash hands with either a nonantimicrobial soap and water or an antimicrobial soap and water (categorization of recommendation: IA)
• If hands are not visibly soiled, use an alcohol-based hand rub for routinely decontaminating hands in all other clinical situations described below (categorization of recommendation: IA). Alternatively, wash hands with an antimicrobial soap and water in all clinical situations described below (categorization of recommendation: IB).
• Decontaminate hands before having direct contact with patients (categorization of recommendation: IB).
• Decontaminate hands before donning sterile gloves when inserting an intravascular catheter (categorization of recommendation: IB).
• Decontaminate hands before inserting indwelling urinary catheters, peripheral vascular catheters, or other invasive devices that do not require a surgical procedure (categorization of recommendation: IB).
• Decontaminate hands after contact with a patient's intact skin (categorization of recommendation: IB).
• Decontaminate hands after contact with body fluids or excretions, mucous membranes, nonintact skin, and wound dressings if hands are not visibly soiled (categorization of recommendation: IB).
• Decontaminate hands if moving from a contaminated body site to a clean body site during patient care (categorization of recommendation: II).
• Decontaminate hands after contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient (categorization of recommendation: II).
• Decontaminate hands after removing gloves (categorization of recommendation: IB).
• Before eating and after using a restroom, wash hands with a nonantimicrobial soap and water or with antimicrobial soap and water (categorization of recommendation: IB).
• Antimicrobial-impregnated wipes may be considered as an alternative to washing hands with nonantimicrobial soap and water. Because they are not as effective as alcohol-based hand rubs or washing hands with an antimicrobial soap and water for reducing bacterial counts on the hands of healthcare workers, they are not a substitute for hand antisepsis (categorization of recommendation: IB).
• Wash hands with nonantimicrobial soap and water or with antimicrobial soap and water if exposure to *Bacillus anthracis* is suspected or proven (categorization of recommendation: II).
• No recommendation can be made regarding the routine use of non–alcohol-based hand rubs for hand hygiene in healthcare settings. Unresolved issue.
CDC/Healthcare Infection Control Practices Advisory Committee System for Categorizing Recommendations
Category IA: Strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies.
Category IB: Strongly recommended for implementation and supported by certain experimental, clinical, or epidemiologic studies and using theoretical rationale.
Category IC: Required for implementation, as mandated by federal or state regulation or standard.

Category II: Suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretic rationale.
No recommendation; Unresolved issue: Practices for which insufficient evidence or no consensus regarding efficacy exists.

Adapted from Boyce JM, Pittet D; Healthcare Infection Control Practices Advisory Committee: Guideline for hand hygiene in health-care settings: recommendations of the Healthcare Infection Control Practices Advisory Committee and the HIPAC/SHEA/APIC/IDSA Hand Hygiene Task Force, *Am J Infect Control* 30(8):S1–S46, 2002.

Central Line–Associated Bloodstream Infection

Hand hygiene is the most important intervention to prevent CLABSI in the NICU. “Care bundles” have been studied in numerous neonatal populations and found to reduce catheter-related infection. **Insertion bundles** include a combination of barrier precaution, hand hygiene standards, skin disinfection, dedicated teams and equipment, catheter site evaluation, checklists, and empowerment to stop the procedure. **Maintenance bundles** include recommendations for aseptic technique when accessing the line, dressing change protocols, and prompt removal when the line is no longer required (Table 130.4).

Table 130.4

Interventions to Prevent Catheter-Related Infections

• Perform effective hand hygiene before and after any interaction with the catheter.
• Use sterile gowns, gloves, drapes, cap, and mask during catheter insertion.
• Disinfect skin with appropriate agent (chlorhexidine is most often used in United States; other disinfectants may be as effective).
• Use a transparent, semipermeable dressing to cover catheter site.
• Change the dressing when soiled or loose.
• Scrub access point with alcoholic chlorhexidine for at least 15 sec.
• Use aseptic nontouch technique to access the catheter.
• Change administration sets no more frequently than 96 hr unless required by the infused product.
• Avoid use of systemic prophylactic antibiotics for catheter insertion.
• Evaluate daily, and remove central venous catheter when no longer required.
• Ensure all healthcare professionals who interact with the patient are educated on central line management.

Adapted from Taylor JE, McDonald SJ, Tan K: Prevention of central venous catheter–related infection in the neonatal unit: a literature review, *J Matern Fetal Neonatal Med* 28(10):1224–1230, 2015.

Ventilator-Associated Pneumonia

VAP prevention bundles have been applied to adult patients but are not readily adapted to premature infants. Thus far, few studies have demonstrated efficacy of infection control measures in preventing VAP in NICUs. A number of measures are believed to be helpful, including caregiver education, hand hygiene, donning of gloves when in contact with secretions, minimizing days of ventilation to the extent possible, suctioning the oropharynx, and removing condensate from the ventilator circuit.

Early Feeding and Human Milk

Several studies have demonstrated benefit to feeding infants maternal milk. Enteral feeding of human milk within 2-3 days of life is associated with decreased rates of necrotizing enterocolitis and nosocomial infection. Human milk contains a number of factors thought to contribute to beneficial effects, including secretory antibody, lactoferrin, phagocytes, and oligosaccharides that shape the neonatal microbial community. Interestingly, the benefits of human milk are not as evident when the milk comes from a donor other than the infant's mother, suggesting important compositional differences in maternal milk.

Antifungal Prophylaxis

Prophylactic administration of **fluconazole** during the 1st 6 wk of life reduces fungal colonization and invasive fungal infection in ELBW infants (<1000 g). In addition to the individual benefit afforded by prophylaxis for VLBW neonates, fluconazole prophylaxis may have a community impact by decreasing the overall fungal burden of a NICU. Results from more than 14 trials at multiple institutions with 3,100 neonates suggests that fluconazole prophylaxis decreases colonization of the urine, GI tract, and integument, without promoting the development of resistance and without adverse effects. Based on an annual U.S. preterm birth cohort of approximately 30,000 VLBW infants, fluconazole prophylaxis could prevent an estimated 2,000-3,000 cases of invasive candidiasis, 200-300 deaths, and the adverse neurodevelopmental outcomes of invasive candidiasis in 400-500 infants per year. Differing baseline rates of fungal infections, practices related to central venous catheter removal, severity of illness, and administration practices for broad-spectra antimicrobials make universal recommendations regarding prophylaxis challenging. A meta-analysis using patient-level data found that fluconazole prophylaxis was effective at preventing colonization and invasive *Candida* infection and was not associated with adverse drug reactions or increased rates of fluconazole resistance.

Neonatal practices that may reduce the risks of invasive candidiasis include limited use of broad-spectrum antimicrobials, use of an aminoglycoside instead of a cephalosporin for empirical therapy when meningitis or antimicrobial resistance is not suspected, limitation of postnatal corticosteroid use in VLBW infants, early enteral feeding, and establishment of the neonatal gut microbiome with human milk feeding.

Nasal Decolonization

Staphylococcus aureus is the 2nd most common cause of HAI in neonatal units. MSSA generally causes more invasive infections than MRSA, but most prevention efforts have been focused on MRSA. Several studies have documented MRSA transmission within the NICU and have identified nasal colonization as an important risk factor for subsequent invasive infection. Various measures have been implemented in attempt to decrease transmission and invasive infection, including contact precautions, cohorting and isolation, and **nasal decolonization** with **mupirocin** . Contact precautions have been associated with decreased rates of MRSA infection in NICU patients. Studies in other patient populations (predominantly adults undergoing peritoneal dialysis) found increased rates of gram-negative infection in those receiving mupirocin treatment. However, a recent multicenter study of mupirocin use in the NICU found a 64% decrease in gram-positive infections, with no change in gram-negative infection rates, among 384 treated infants.

CHAPTER 131

Congenital and Perinatal Infections

Felicia A. Scaggs Huang, Rebecca C. Brady

Infections are a frequent and important cause of neonatal morbidity and mortality. **Congenital** or **intrauterine** infections (i.e., those transmitted across the placenta) and **perinatal** infections (i.e., those transmitted from the mother to the fetus or newborn infant during the birth process) represent 2 major routes of neonatal infection.

131.1

Congenital Infections

Felicia A. Scaggs Huang, Rebecca C. Brady

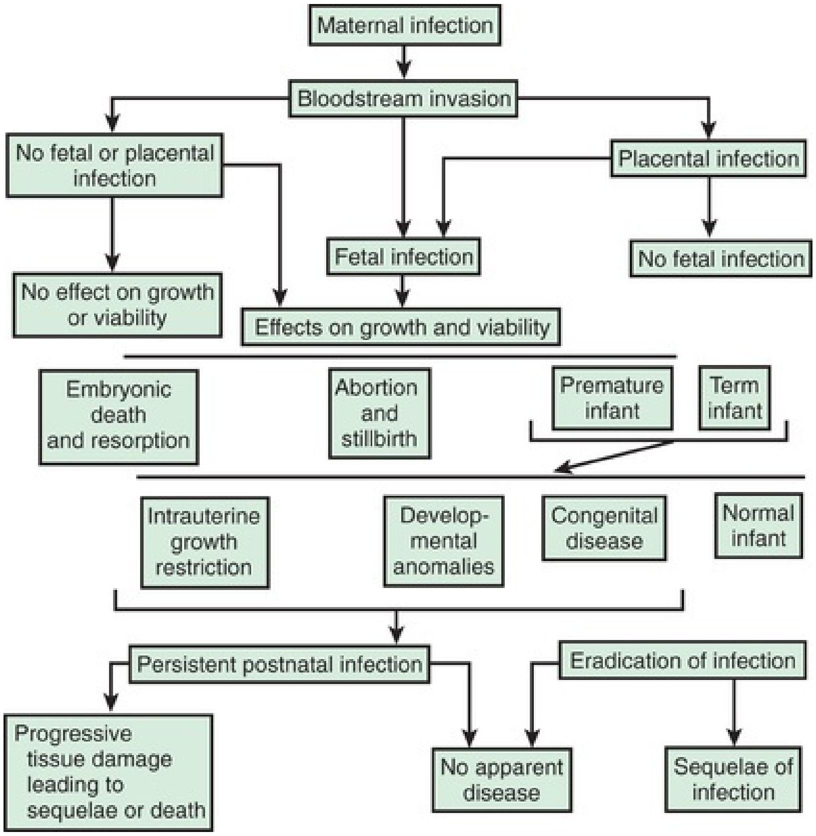
As many as 2% of fetuses are infected in utero; disease can be acquired prenatally from a wide variety of etiologic agents, including bacteria, viruses, fungi, and protozoa. Clinical manifestations can range from asymptomatic or subclinical to life-threatening disease. History and physical examination findings provide insight into the best approach for this immunologically immature population. (See Fig. 129.2 and Table 129.2 in Chapter 129 .)

General Approach

Infectious as well as noninfectious processes, such as underlying congenital heart disease, genetic disorders, and inborn errors of metabolism, should be considered in the differential diagnosis of congenital and perinatal infections. Because maternal infection is a prerequisite for infection in the fetus, a thorough history is essential to assess the mother for her symptoms, travel, diet, medication use, occupational exposures, and any **sexually transmitted infections (STIs)** during pregnancy. Clinical manifestations are varied and overlap for many of the pathogens causing intrauterine infection. Laboratory testing and/or radiologic imaging is often required to confirm the diagnosis. Treatment depends on the specific pathogen and can range from symptomatic management with close follow-up for long-term sequelae to targeted antimicrobial therapy.

Pathogenesis

The route and timing of infection can provide helpful clues as to the potential infectious etiology (Fig. 131.1 and Table 131.1). First-trimester infection may alter embryogenesis and result in malformations of the heart and eyes, as seen in congenital rubella syndrome. Third-trimester infection (e.g., congenital toxoplasmosis) can result in active infection with signs of hepatomegaly, splenomegaly, and generalized lymphadenopathy at birth. Infections that occur late in gestation (e.g., congenital syphilis) may lead to a delay in clinical manifestations until weeks to years after birth.



Maternal infection
Bloodstream invasion
No fetal or placental infection
Placental infection
Fetal infection
No fetal infection
No effect on growth or viability
Effects on growth and viability
Embryonic death and resorption
Abortion and stillbirth
Premature infant
Term infant
Intrauterine growth restriction
Develop-mental anomalies
Congenital disease
Normal infant
Persistent postnatal infection
Eradication of infection
Progressive tissue damage leading to sequelae or death
No apparent disease
Sequelae of infection

CMV , Cytomegalovirus; *HBV* , hepatitis B virus; *HIV* , human immunodeficiency virus; *HSV* , herpes simplex virus; *LCV* , lymphocytic choriomeningitis virus; *VZV* , varicella-zoster virus.

From Maldonado YA, Nizet V, Klein JO, et al: Current concepts of infections of the fetus and newborn infant. In Wilson CB, Nizet V, Maldonado Y, et al, editors: *Remington and Klein's infectious diseases of the fetus and newborn,* ed 8, Philadelphia, 2016, Elsevier (Table 1-5).

Intrauterine infection from cytomegalovirus (CMV), *Treponema pallidum* , *Toxoplasma gondii* , rubella virus, varicella-zoster virus (VZV), and human parvovirus B19 may cause minimal or no symptoms in the mother but still may be transmitted across the placenta to the fetus. The presence of maternal antibodies to rubella prevents infection, but transmission of CMV can occur despite preexisting antibodies. Regardless of the mother's immune status, the placenta may act as a barrier, and the fetus may or may not be infected. If infection occurs, signs may or may not be noted in the fetus during pregnancy. Infection can result in spontaneous abortion, congenital malformation, intrauterine growth restriction (IUGR), premature birth, stillbirth, acute or delayed disease in the neonate, or asymptomatic persistent infection with sequelae later in life.

Clinical Manifestations

The clinical manifestations of intrauterine infections can range from asymptomatic to severe multiorgan system complications. For some agents (e.g., CMV, *T. pallidum*), ongoing injury after birth leads to late sequelae. The specific clinical signs in the newborn period are usually not sufficient to make a definitive diagnosis but are useful to guide more specific laboratory testing. Symptomatic congenital infections often affect the central nervous system (CNS; brain and eyes) and the reticuloendothelial system (RES; bone marrow, liver, and spleen). Table 131.2 presents the clinical manifestations of some specific congenital infections. Congenital Zika virus infection has features that are rarely seen with other congenital infections (Table 131.3). No hematologic or hepatic laboratory abnormalities have been documented in infants with congenital Zika virus infection. Table 131.4 provides late sequelae of some congenital infections.

Diagnosis

During Pregnancy

The presence of IUGR or a physical abnormality on a prenatal fetal ultrasound raises concern for a congenital infection. The well-known acronym **TORCH** —***T*** *oxoplasma gondii* , **O** ther (*Treponema pallidum* , human parvovirus B19, HIV, Zika virus, others), **R** ubella, **C** ytomegalovirus, and **H** erpes simplex virus (HSV)—is a useful mnemonic. However, the routine ordering of TORCH serology panels is *not* recommended because the presence of a TORCH agent IgG antibody in the mother indicates past infection but does not establish if the infection occurred during pregnancy. Maternal IgM titers to *specific* pathogens are only moderately sensitive, and a negative result cannot be used to exclude infection.

In certain cases, a fetal blood sample with cordocentesis can be obtained and tested for total and pathogen-specific IgM assays, polymerase chain reaction assays (PCRs), or cultures. A total IgM concentration is a helpful screening test because a normal fetal IgM is <5 mg/dL, so any elevation in total IgM may indicate an underlying infection. A positive *pathogen-specific* IgM test is strongly suggestive of infection, but a negative test does not rule out the organism as the cause of the fetopathy. Amniotic fluid can also be obtained and sent for PCR or culture. The presence of CMV, *T. gondii* , or human parvovirus B19 in amniotic fluid indicates the fetus likely is infected but cannot establish the severity of disease. Although HSV is included in the TORCH acronym, it is rarely isolated from amniotic fluid and is rarely transmitted across the placenta from mother to fetus. Fetal blood can be collected to test for human parvovirus B19 IgM and PCR.

Newborn Infant

When a congenital infection is suspected because clinical signs are present, a complete blood count with differential and platelet count along with measurements of transaminases and total/direct bilirubin are routinely performed. Additional evaluations may include a dilated funduscopic examination, auditory brainstem response (ABR) for those failing the newborn hearing screen, and CNS imaging. If available, pathologic examination of the placenta may be informative. Infectious diseases consultation is valuable in guiding the evaluation.

Neonatal antibody titers for specific pathogens are often difficult to interpret because IgG is acquired from the mother by transplacental passage, and a positive result may reflect the mother's past infection and *not* infection of the newborn. Neonatal IgM antibody titers to specific pathogens have high specificity and only moderate sensitivity; a negative result cannot be used to exclude infection. Paired maternal and fetal-neonatal IgG antibody titers showing higher or rising infant IgG antibodies can diagnose some congenital infections (e.g., syphilis). Total cord blood IgM and IgA are not actively transported across the placenta to the fetus and are not specific for intrauterine infection.

Although viral culture has long been considered the standard for CMV and other viral infections, PCR is sensitive, specific, and now widely accepted. The Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL; Palo Alto, CA: www.pamf.org/serology/ ; telephone: (650) 853-4828; e-mail: toxolab@pamf.org) offers specialized tests and physician experts to aid in the diagnosis of congenital toxoplasmosis. If there is concern for congenital Zika virus infection, healthcare providers should refer to the Centers for Disease Control and Prevention (CDC) Guidance for US Laboratories Testing for Zika Virus Infection (www.cdc.gov/zika/laboratorie/lab-guidance.html) to assist in collecting and sending appropriate laboratory tests from the mother, newborn infant, placenta, and umbilical cord. Currently, testing for Zika virus with real-time reverse-transcription PCR (rRT-PCR) and IgM enzyme-linked immunosorbent assay (ELISA) from neonatal urine and serum specimens is recommended. However, the most reliable method of testing has not been established. In endemic areas, this workup should be done within 2 days of delivery because it is difficult to distinguish congenital from postnatal infection if testing is done later.

Specific Infectious Agents

Important congenital infections include more than the TORCH agents. The following is a list of pathogens that may be transmitted across the placenta and the respective chapters where they are discussed in more detail, including treatment.

Bacteria

- *Listeria monocytogenes* (Chapter 215)
- Syphilis (*Treponema pallidum*) (Chapter 245)

Viruses

- Cytomegalovirus (Chapter 282)
- Hepatitis B (Chapter 385)
- Hepatitis C (Chapter 385)
- Herpes simplex virus (Chapter 279)
- Human immunodeficiency virus (Chapter 302)
- Human parvovirus B19 (Chapter 278)
- Lymphocytic choriomeningitis virus (Chapter 298)
- Rubella (Chapter 274)

Varicella-zoster virus (Chapter 280)
Zika virus (Chapter 294.12)

Parasite

Toxoplasmosis (*Toxoplasma gondii*) (Chapter 316)

131.2

Perinatal Infections

Felicia A. Scaggs Huang, Rebecca C. Brady

Perinatal infections are defined as those that are transmitted from the mother to the fetus or newborn infant during the birth process. Despite recommended universal screening of pregnant women for *Chlamydia trachomatis* and gonorrhea, transmission to the newborn still occurs. In addition to these STIs, other bacteria, viruses, and *Candida* spp. may cause perinatal infections. Similar to congenital infections, their presentation can range from asymptomatic to a sepsis-like syndrome.

General Approach

The general approach is similar to that for congenital infections and includes a detailed maternal history and a careful examination of the newborn **(** see Chapter 129). Many clinical syndromes overlap, and therefore laboratory testing is usually required to establish a specific microbiologic etiology and guide management decisions.

Pathogenesis

The human birth canal is colonized with aerobic and anaerobic bacteria. **Ascending amniotic infection** may occur with either apparently intact membranes or relatively brief duration of membrane rupture. Infectious agents can also be acquired as the newborn infant passes through the vaginal canal. This acquisition may result in either colonization or disease. Factors influencing which colonized infants will experience disease are not well understood but include prematurity, underlying illness, invasive procedures, inoculum size, virulence of the infecting organism, genetic predisposition, the innate immune system, host response, and transplacental maternal antibodies.

Chorioamnionitis has been historically used to refer to microbial invasion of the amniotic fluid, often as a result of prolonged rupture of the chorioamniotic membrane for >18 hr. The term *chorioamnionitis* is confusing because it does not convey the spectrum of inflammatory or infectious diseases, it leaves out other intrauterine components that can be involved (e.g., decidua), and it results in significant variability in clinical practice, with the potential for a significant number of well newborns being exposed to antimicrobial agents. The term **intrauterine inflammation or infection at birth** , abbreviated as **Triple I** , has become more accepted because of the heterogeneous nature of conditions that can affect the mother and neonate (Table 131.5). Regardless of the definition used, prematurity (<37 wk) is associated with a greater risk of early-onset sepsis, especially with group B streptococcus.

Table 131.5

Classification of Triple I and Isolated Maternal Fever

TERMINOLOGY	FEATURES
Isolated maternal fever	Maternal oral temperature ≥39°C is considered a "documented fever." If the oral temperature is ≥38°C but ≤39°C, repeat the measurement in 30 min. If the repeat value is ≥38°C, it is considered a "documented fever."
Suspected Triple I	Fever without a clear source with *any* of the following:
	1. Baseline fetal tachycardia (>160 beats/min for 10 min) 2. Maternal WBC >15,000/mm^3 3. Purulent fluid from the cervical os
Confirmed Triple I	All the above (from suspected Triple I) with *any* of the following:
	1. Amniocentesis-proven infection through positive Gram stain 2. Low glucose of amniotic fluid or positive amniotic fluid culture 3. Placental pathology consistent with infection

Triple I, Intrauterine inflammation or infection at birth; WBC, white blood cell count.

Adapted from Higgins RD, Saade G; Chorioamnionitis Workshop participants: Evaluation and management of women and newborns with a maternal diagnosis of chorioamnionitis: summary of a workshop, *Obstet Gynecol* 127(3):426–436, 2016.

Aspiration or ingestion of bacteria in amniotic fluid may lead to congenital pneumonia or systemic infection, with manifestations becoming apparent before delivery (fetal distress, tachycardia), at delivery (failure to breathe, respiratory distress, shock), or after a latent period of a few hours (respiratory distress, shock). Aspiration or ingestion of bacteria during the birth process may lead to infection after an interval of 1-2 days.

Clinical Manifestations

Most perinatal infections present clinically during the 1st mo of life. Initial signs and symptoms may be either nonspecific or focal (see Chapter 129). Additional information on specific infectious agents and their management are reviewed in the chapters indicated below.

Specific Infectious Agents

Bacteria

Chlamydia trachomatis (Chapter 253)
Escherichia coli (Chapter 227)
Genital mycoplasmas (Chapter 251)
Group B streptococci (Chapter 211)
Neisseria gonorrhoeae (Chapter 219)
Syphilis (*Treponema pallidum*) (Chapter 245)

Viruses

Cytomegalovirus (Chapter 282)
Enteroviruses (Chapter 277)
Hepatitis B (Chapter 385)
Herpes simplex virus (Chapter 279)
Human immunodeficiency virus (Chapter 302)

Fungi

Candida spp. (Chapter 261)

Diagnosis

The maternal history provides important information about maternal exposures to infectious diseases, bacterial colonization, immunity (natural and acquired), and obstetric risk factors (prematurity, prolonged ruptured membranes, chorioamnionitis). STIs acquired by a pregnant woman, including syphilis, *N. gonorrhoeae* , and *C. trachomatis*, have the potential for perinatal transmission.

Neonates with perinatal infections often present with nonspecific symptoms and signs; therefore the general diagnostic evaluation for the ill neonate as discussed in Chapter 202 should be followed. Table 131.6 provides a summary of laboratory tests that are useful to diagnose specific perinatal infections.

Table 131.6

Laboratory Tests in the Diagnosis of Specific Perinatal Infections

INFECTIOUS AGENT	ACCEPTABLE SPECIMEN(S) FROM INFANT UNLESS OTHERWISE INDICATED	LABORATORY TEST
Chlamydia trachomatis	Conjunctiva, nasopharyngeal swab, tracheal aspirate	Culture using special transport media Nucleic acid amplification tests (NAATs) are not FDA-approved for specimens from neonates.*
Genital mycoplasmas (*Mycoplasma hominis* , *M. genitalium* , *Ureaplasma urealyticum*)	Tracheal aspirate, blood, or cerebrospinal fluid (CSF)	Culture using special transport media Real-time polymerase chain reactions (PCRs)
Neisseria gonorrhoeae	Conjunctiva, blood, CSF, or synovial fluid	Finding gram-negative intracellular diplococci on Gram stain is suggestive. Culture on special media establishes the diagnosis.
Syphilis (*Treponema pallidum*)	Serum (mother)	Rapid plasma reagin (RPR) and if reactive, a specific treponemal test †
	Serum	RPR
	CSF	Venereal Disease Research Laboratories (VDRL)
Cytomegalovirus	Urine, saliva, blood, or CSF	PCR for detection of CMV DNA

		Obtain within 2-4 wk of birth.
Enteroviruses	Blood, nasopharyngeal swab, throat swab, conjunctival swab, tracheal aspirate, urine, stool, rectal swab, or CSF	PCR Cell culture (sensitivity depends on serotype and cell lines used)
Hepatitis B	Serum (mother)	Hepatitis B surface antigen (HBsAg)
	Serum	If mother's HBsAg is positive, at age 9 mo, test the infant for HBsAg and hepatitis B surface antibody.
Herpes simplex viruses 1 and 2	Conjunctiva, skin vesicle scraping, whole blood, or mouth vesicles	PCR or cell culture
	CSF	PCR
	“Surface cultures” (mouth, nasopharynx, conjunctiva, and anus)	PCR or cell culture
Human immunodeficiency virus (HIV)	Serum (mother)	Fourth-generation HIV antigen/antibody test
	Whole blood	HIV DNA PCR
Candida species	Blood, skin biopsy, or CSF	Culture
Zika virus	Blood, urine, CSF	NAT and serum IgM NAT may be falsely negative IgG antibodies may reflect maternal exposure Antibodies may cross react with other flaviviruses

[*] Published evaluations of NAATs for these indications are limited, but sensitivity and specificity is expected to be at least as high as those for culture. FDA, U.S. Food and Drug Administration.

[†] Treponemal tests include the *T. pallidum* particle agglutination (TP-PA) test, *T. pallidum* enzyme immunoassay (TP-EIA), *T. pallidum* chemiluminescent assay (TP-CIA), and fluorescent treponemal antibody absorption (FTA-ABS) test.

Adolescent Physical and Social Development

Cynthia M. Holland-Hall

See also Part XV and Chapters 577 and 578 .

During the preteen, teenage, and young adult years, young people undergo not only dramatic changes in physical appearance, but also rapid changes in physiologic, psychological, and social functioning. Hormonally driven physiologic changes and ongoing neurologic development occur in the setting of social structures that foster the transition from childhood to adulthood. This period of development comprises **adolescence** , which is divided into 3 phases—early, middle, and late adolescence—each marked by a characteristic set of biologic, cognitive, and psychosocial milestones (Table 132.1). Although individual variations in the timing and pace of development undoubtedly exist, these changes follow a fairly predictable pattern of occurrence. Gender and culture profoundly affect the developmental course, as do physical, social, and environmental influences. Given the interaction of these domains, a biopsychosocial perspective is best suited to approach the healthcare of the adolescent.

Table 132.1

Milestones in Early, Middle, and Late Adolescent Development

VARIABLE	EARLY ADOLESCENCE	MIDDLE ADOLESCENCE	LATE ADOLESCENCE
Approximate age range	10-13 yr	14-17 yr	18-21 yr
Sexual maturity rating*	1-2	3-5	5

Physical	Females: secondary sex characteristics (breast, pubic, axillary hair), start of growth spurt Males: testicular enlargement, start of genital growth	Females: peak growth velocity, menarche (if not already attained) Males: growth spurt, secondary sex characteristics, nocturnal emissions, facial and body hair, voice changes Change in body composition Acne	Physical maturation slows Increased lean muscle mass in males
Cognitive and moral	Concrete operations Egocentricity Unable to perceive long-term outcome of current decisions Follow rules to avoid punishment	Emergence of abstract thought (formal operations) May perceive future implications, but may not apply in decision-making Strong emotions may drive decision-making Sense of invulnerability Growing ability to see others' perspectives	Future-oriented with sense of perspective Idealism Able to think things through independently Improved impulse control Improved assessment of risk vs reward Able to distinguish law from morality
Self-concept/identity formation	Preoccupied with changing body Self-consciousness about appearance and attractiveness	Concern with attractiveness Increasing introspection	More stable body image Attractiveness may still be of concern Consolidation of identity
Family	Increased need for privacy Exploration of boundaries of dependence vs independence	Conflicts over control and independence Struggle for greater autonomy Increased separation from parents	Emotional and physical separation from family Increased autonomy Reestablishment of “adult” relationship with parents
Peers	Same-sex peer affiliations	Intense peer group involvement Preoccupation with peer culture Conformity	Peer group and values recede in importance
Sexual	Increased interest in sexual anatomy Anxieties and questions about pubertal changes Limited capacity for intimacy	Testing ability to attract partner Initiation of relationships and sexual activity Exploration of sexual identity	Consolidation of sexual identity Focus on intimacy and formation of stable relationships Planning for future and commitment

[*] See text and Figs. 132.1 and 132.2 .

Physical Development

Puberty is the biologic transition from childhood to adulthood. Pubertal changes include the appearance of the secondary sexual characteristics, increase in height, change in body composition, and development of reproductive capacity. Adrenal production of androgen, mainly dehydroepiandrosterone sulfate (DHEAS), may occur as early as 6 yr of age, with development of underarm odor and faint genital hair (**adrenarche**). Maturation of the gonadotropin-releasing hormone (GnRH) pulse generator is among the earliest neuroendocrine changes associated with the onset of puberty. Under the influence of GnRH, the pituitary gland secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH); initially this occurs in a pulsatile fashion primarily during sleep, but this diurnal variation diminishes throughout puberty. LH and FSH stimulate corresponding increases in gonadal androgens and estrogens. The triggers for these changes are incompletely understood but may be mediated in part by the hormone leptin, high concentrations of which are associated with increased body fat and earlier onset of puberty. Both genetic and environmental (epigenetic) contributions to the regulation of pubertal timing are likely.

Sexual Development

The progression of the development of the secondary sex characteristics may be described using the **sexual maturity rating (SMR)** scale (ranging from 1, preadolescence, to 5, sexual maturity), or **Tanner stages** . Figs. 132.1 and 132.2 depict the physical findings of breast and pubic hair maturation at each SMR (Tables 132.2 and 132.3). Although the ages at which individual pubertal changes occur may vary, the timing and sequence of these changes relative to one another is predictable (Figs. 132.3 and 132.4). The wide range of normal progress through sexual maturation is affected by genetics, the psychosocial environment, nutrition, and overall health status. Environmental exposures may play a role as well.

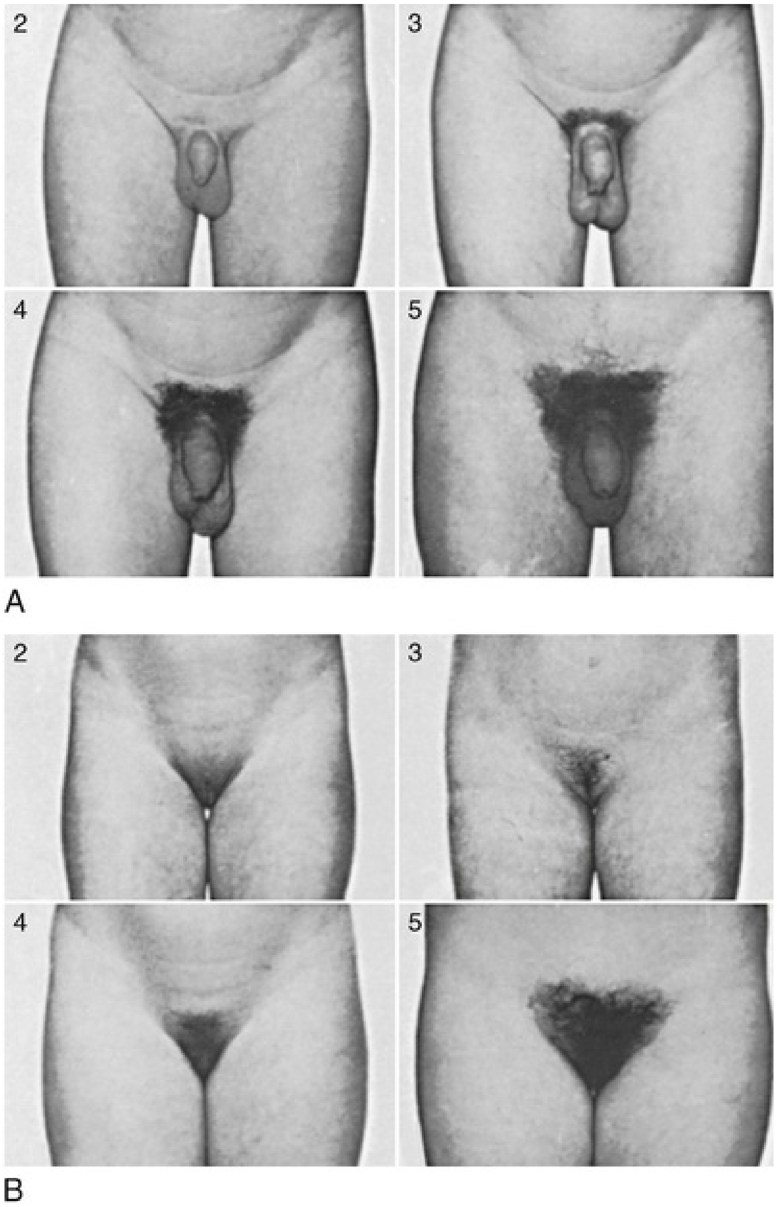

FIG. 132.1 Sexual maturity ratings (2-5) of pubic hair changes in adolescent males (**A**) and females (**B**) (see Tables 132.2 and 132.3). (Courtesy of J.M. Tanner, MD, Institute of Child Health, Department for Growth and Development, University of London.)

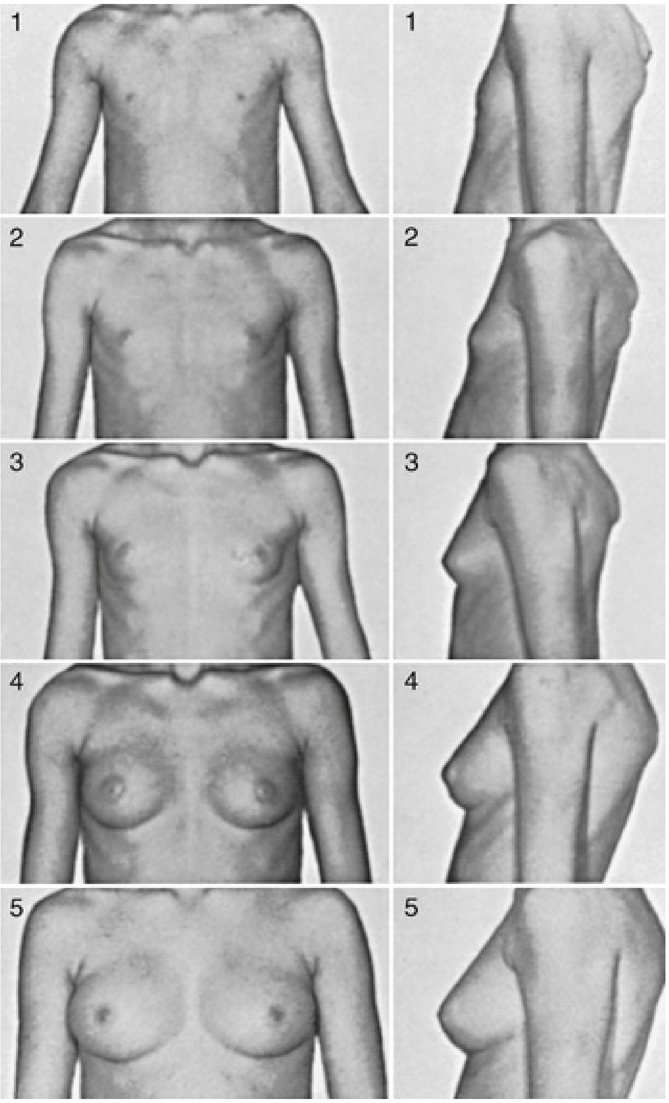

FIG. 132.2 Sexual maturity ratings (1-5) of breast changes in adolescent females. (Courtesy of J.M. Tanner, MD, Institute of Child Health, Department for Growth and Development, University of London.)

Table 132.2

Sexual Maturity Rating (SMR) Stages in Females

SMR STAGE	PUBIC HAIR	BREASTS
1	Preadolescent	Preadolescent
2	Sparse, lightly pigmented, straight, medial border of labia	Breast and papilla elevated as small mound; diameter of areola increased
3	Darker, beginning to curl, increased amount	Breast and areola enlarged, no contour separation
4	Coarse, curly, abundant, but less than in adult	Areola and papilla form secondary mound

5	Adult feminine triangle, spread to medial surface of thighs	Mature, nipple projects, areola part of general breast contour

From Tanner JM: *Growth at adolescence,* ed 2, Oxford, England, 1962, Blackwell Scientific.

Table 132.3

Sexual Maturity Rating (SMR) Stages in Males

SMR STAGE	PUBIC HAIR	PENIS	TESTES
1	None	Preadolescent	Preadolescent
2	Scant, long, slightly pigmented	Minimal change/enlargement	Enlarged scrotum, pink, texture altered
3	Darker, starting to curl, small amount	Lengthens	Larger
4	Resembles adult type, but less quantity; coarse, curly	Larger; glans and breadth increase in size	Larger, scrotum dark
5	Adult distribution, spread to medial surface of thighs	Adult size	Adult size

From Tanner JM: *Growth at adolescence,* ed 2, Oxford, England, 1962, Blackwell Scientific.

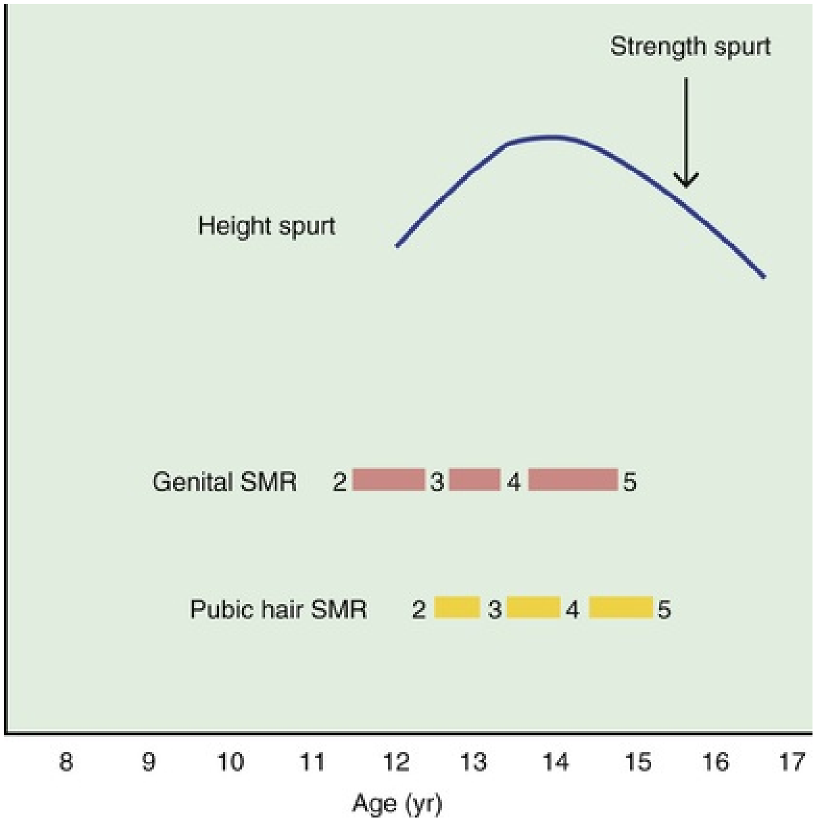

FIG. 132.3 Sequence of pubertal events in males. Although the age of

onset of puberty is variable, the sequence of events relative to one another is predictable. SMR, Sexual maturity rating.

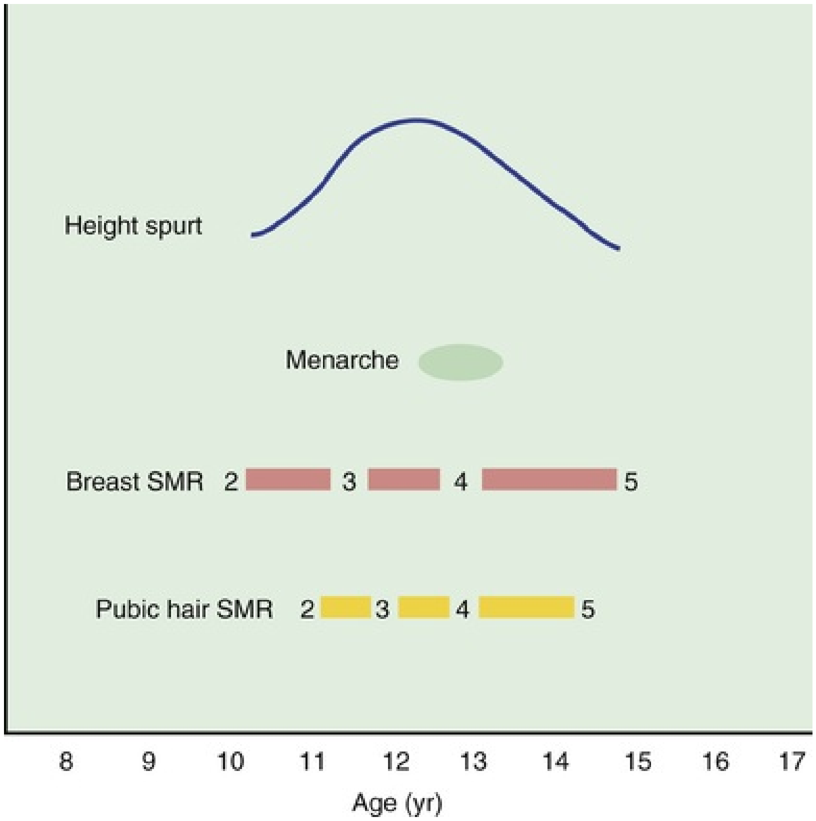

FIG. 132.4 Sequence of pubertal events in females. Although the age of onset of puberty is variable, the sequence of events relative to one another is predictable. SMR, Sexual maturity rating.

In **males** the first visible sign of puberty and the hallmark of SMR 2 is testicular enlargement, beginning as early as 9.5 yr, followed by the development of pubic hair. This is followed by penile growth during SMR 3. Peak growth occurs when testis volumes reach approximately 9-10 cm^3 during SMR 4. Under the influence of LH and testosterone, the seminiferous tubules, epididymis, seminal vesicles, and prostate enlarge. Sperm may be found in the urine by SMR 3; nocturnal emissions may be noted at this time as well. Some degree of breast tissue growth, typically bilateral, occurs in 40–65% of males during SMR 2-4 as a presumed consequence of a relative excess of estrogenic stimulation. This usually resolves with ongoing maturation.

In **females** , typically the first visible sign of puberty and the hallmark of

SMR 2 is the appearance of breast buds (**thelarche**), between 7 and 12 yr of age. A significant minority of females develops pubic hair (**pubarche**) prior to thelarche. Less visible changes include enlargement of the ovaries, uterus, labia, and clitoris and thickening of the endometrium and vaginal mucosa. A clear vaginal discharge may be present before menarche (physiologic leukorrhea). Menses typically begins within 3 yr of thelarche, during SMR 3-4 (average age 12.5 yr; normal range 9-15 yr) (see Fig. 132.4). The timing of **menarche** is determined largely by genetics; contributing factors likely include adiposity, chronic illness, nutritional status, and the physical and psychosocial environment. Early menstrual cycles often are anovulatory and thus somewhat irregular, but typically occur every 21-45 days and include 3-7 days of bleeding, even during the 1st year following menarche.

The **onset of puberty** and menarche appear to be occurring at earlier ages than previously reported in the United States. Several studies from 1948–1981 identified the average age for the onset of breast development as ranging from 10.6-11.2 yr of age. Multiple reports since 1997 suggest a significantly earlier average age of onset, ranging from 8.9-9.5 yr in black females to 10.0-10.4 yr in white females. Almost 25% of black females and 10% of white females initiate breast development by 7 yr of age. Early breast development may be associated with a slower tempo of puberty (i.e., longer time to menarche). There also appears to be a trend toward decreasing ages for the onset of pubic hair development and menarche. Data from the National Health and Nutrition Examination Survey (NHANES), a nationally representative, longitudinal survey in the United States, show a decline in the average age of menarche of 4.9 mo between the 1960s and 2002. Changes in the timing of menarche *within* ethnic groups, however, were significantly smaller. The larger change seen in the population as a whole may be partially explained by changes in the ethnic makeup of the sample. The reasons for the larger decrease in age for breast development have been postulated to include the epidemic of childhood obesity as well as exposure to estrogen-like environmental toxins (endocrine disruptors), but further research in this area is needed.

Although fewer data are available on changes in the timing of puberty in males, they appear to be experiencing a similar trend. Although the method of assessing the onset of puberty (i.e., inspection vs. palpation of the testes) varies between studies, it appears that the average age for the onset of genital and pubic hair development may have decreased by 1-2 yr over the past several decades in many industrialized countries. Evidence for an association of obesity with the timing of puberty in males has been inconsistent.

Somatic Growth

Linear growth acceleration begins in early adolescence for both genders, with 15–20% of adult height accrued during puberty. Females attain a **peak height velocity (PHV)** of 8-9 cm/yr at SMR 2-3, approximately 6 mo before menarche. Males typically begin their growth acceleration at a later SMR stage, achieve a PHV of 9-10 cm/yr later in the course of puberty (SMR 3-4), and continue their linear growth for approximately 2-3 yr after females have stopped growing (Fig. 132.5). The growth spurt begins distally, with enlargement of the hands and feet, followed by the arms and legs, and finally the trunk and chest. This growth pattern imparts a characteristic “awkward” appearance to some early adolescents. Body composition changes as well, after attainment of PHV. Males undergo an increase in lean body mass (“strength spurt”), whereas females develop a higher proportion of body fat. Scoliosis, if present, may progress with rapid axial skeleton growth (see Chapter 699.1). From 50–65% of total body calcium is laid down during puberty. Bone growth precedes increases in bone mineralization and bone density, which may increase the adolescent's risk of fracture during times of rapid growth. Since skeletal growth precedes muscle growth, sprains and strains may be more common during this time as well.

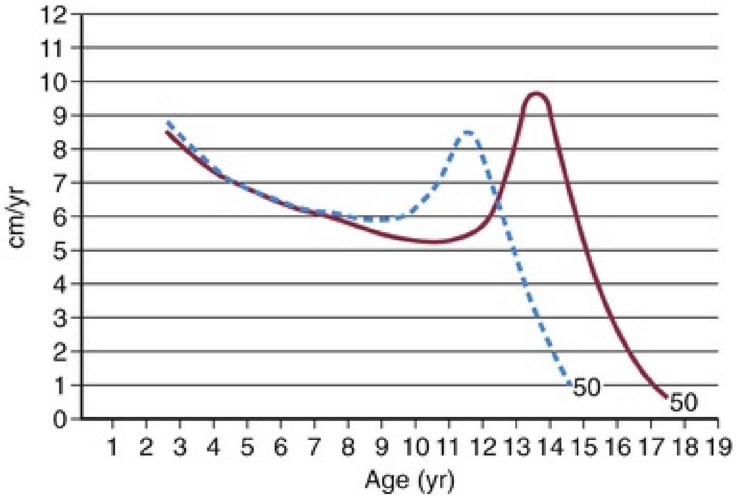

FIG. 132.5 Height velocity curves for American males *(solid line)* and females *(dashed line)* who have their peak height velocity at the average age (i.e., average growth tempo). (From Tanner JM, Davies PSW: Clinical longitudinal standards for height and height velocity for North American

children, *J Pediatr* 107:317, 1985.)

Cardiovascular changes in middle adolescence include increased heart size, higher blood pressure, and increases in blood volume and hematocrit, particularly in males. Coupled with an increase in lung vital capacity, these changes lead to greater aerobic capacity. Androgenic stimulation of sebaceous and apocrine glands may result in acne and body odor. Rapid enlargement of the larynx, pharynx, and lungs leads to changes in vocal quality in males, typically preceded by vocal instability (voice cracking). Elongation of the optic globe may result in the development of myopia (see Chapter 638). Dental changes include jaw growth, loss of the final deciduous teeth, and eruption of the permanent cuspids, premolars, and finally, molars (see Chapter 333). Orthodontic appliances may be needed, secondary to growth exacerbations of bite disturbances. Physiologic changes in sleep patterns and increased sleep requirements occur, causing many adolescents to delay sleep onset at night, with subsequent difficulty awakening for early school start times in the morning (see Chapter 31).

Neurologic, Cognitive, and Moral Development

As children progress through adolescence, they develop and refine their ability to use formal operational thought processes. Abstract, symbolic, and hypothetical thinking replaces the need to manipulate concrete objects. Middle and late adolescents develop the ability to consider multiple options and to assess the long-term consequences of their actions. The capacity for verbal expression is enhanced. Since adolescents' decision-making and subsequent behaviors are the primary determinants of their mortality and morbidity, understanding these cognitive processes is of critical importance.

Both structural and functional brain development continue throughout adolescence. Cortical gray matter volume peaks in preadolescence, then decreases because of selective “pruning” of rarely used synaptic connections. Cerebral white matter volume increases until mid-to-late adolescence, reflecting increasing myelination and subsequent facilitation of integrated brain activity and more efficient transmission of information between different regions of the brain, enhancing the “signal-to-noise” ratio. Although the frontal lobes and prefrontal cortex, regions of the brain associated with executive function, have been considered to be among the last regions to mature, other cortical regions show similarly prolonged trajectories of maturation. Without question, adolescents are capable of the complex cognitive processes attributed to frontal lobe function. *Cognitive control* , however, continues to improve into adulthood, with progressive maturation and *integration* of component processes such as working memory, inhibition and impulse control, performance monitoring, and motivational circuitry.

The behavioral correlates of adolescent neurodevelopment remain speculative but are increasingly supported by a rapidly expanding body of research. Adolescents appear to demonstrate a unique sensitivity to the effects of dopamine on reward-relevant subcortical structures such as the ventral striatum, with some studies demonstrating increased activation in this region when receiving rewards, relative to children or adults. Other studies show reduced responsiveness to aversive stimuli in adolescents. This altered responsiveness to risk vs reward may underlie the increased risk taking and novelty seeking seen in adolescents. Early maturation and distinct patterns of neural reactivity in the amygdala and other limbic structures may explain the strong role that social and emotional stimuli play in adolescents, overwhelming the frontal executive function systems that facilitate the interpretation and regulation of those social and emotional experiences. This may explain why adolescents are more likely to make poor decisions in highly emotionally charged situations, relative to mature adults. These “hot cognition” processes may result in the adolescent making a different decision in the context of a strong affective experience than he or she would in a less emotional state (“cool cognition”). These 2 types of cognitive processes may not develop at the same rate; the adolescent may be able to use higher brain structures and functions more effectively when in states of lower emotional arousal.

Early adolescents often continue to employ the concrete operational cognitive processes of childhood. Although formal operational cognition is developing, it may be applied inconsistently across different domains. A young adolescent may be able to use abstract thought when completing schoolwork, but not when working through a personal dilemma. Early adolescence also is characterized by egocentricity—the belief of some adolescents that they are the center of everyone's attention. Despite being largely imagined, this perception of always being “on stage” can be stressful for adolescents, who may feel that others are constantly judging or evaluating them. Early adolescents express a greater need for privacy than they did in childhood and begin to appreciate the privacy of their own thoughts. With ongoing cognitive development, **middle** adolescents are more able to consider the needs and feelings of other people. Their creativity and intellectual abilities are enhanced. Because of their increased capacity for abstract thought in combination with a persistent perception of uniqueness, middle adolescents may feel a sense of immortality and immunity to the consequences of risky behaviors. **Late** adolescents are more future oriented and able to delay gratification. They can think more independently, consider others' views, and compromise. They have a stronger sense of self and more stable interests. Under times of stress, adolescents may temporarily revert back to the cognitive processes and coping strategies used at younger ages.

Moral development generally accompanies cognitive development. Preadolescents, concrete and individualistic, follow rules in order to please authority figures and avoid punishment. As they move into early adolescence, they develop a stronger sense of right and wrong but are likely to perceive these as absolute and unquestionable. Middle and late adolescents may establish a sense of morality driven by their desire to be seen as a good person, to behave in a manner according to their perceived place in society, or by their sense of obligation to care for others. Moral decision-making, however, still may be highly subject to emotional context. Late adolescents may develop a rational conscience and an independent system of values, although these often are largely consistent with parental values. While going through this complex developmental process, religious or political organizations that promote simple answers to complex social or moral questions may hold great appeal to the adolescent.

Psychosocial Development

In contrast to cognitive development, psychosocial development correlates more strongly with pubertal status and physical maturation than with chronologic age. Whereas cognitive development is more biologically determined, psychosocial development is subject to greater environmental and cultural influences. Indeed, cultural variation can be dramatic. Some late adolescents move immediately from high school into marriage, childbearing, working, and financial independence; others remain dependent on the parents while pursuing their own education for several more years, in a period sometimes referred to as *emerging adulthood* . Psychosocial development also may be nonlinear, with different domains of growth progressing along different timelines. An overriding theme of psychosocial development is the concept of identity formation and consolidation as the adolescent moves away from the nurturing protection of the family, develops an increased affiliation with the peer group(s), and ultimately defines himself or herself as an individual.

Separation from the parents is a hallmark of adolescent development. Early adolescents start to seek out more privacy at home, spending less time with the parents. They begin to reject parental advice and involvement in their decision-making as they explore the boundaries of their dependence on, and independence from, their parents. With evolving cognitive skills, an adolescent can conceive of an ideal parent and contrast this ideal with his or her own parents. Adolescents may seek out alternative adult role models, such as teachers, coaches, or parents of friends. Parent–child conflict often peaks during middle adolescence, with disagreements over privileges, independence, and other limits set by the parents. Adolescents may appear intermittently to seek and reject parental acceptance. It is theorized that perhaps the adolescent *needs* to conceive of the parents as “wrong” in order to ameliorate the pain of separating from them. Throughout this time, however, the parents remain a critical source of nurturing and support for the adolescent and continue to exert significant influence over the adolescent's decision-making. Paradoxically, frequent arguments and conflict may coexist with strong emotional bonds and closeness. The late adolescent may reestablish a more “adult–adult” type of relationship with the parents, once again seeking out and considering parental advice and guidance as they enter adulthood.

Increasing importance of the **peer group** also may buffer the emotional trauma of separating from the parents. Early adolescents tend to socialize largely with same-sex peers, both in their individual friendships and larger groups. Females' peer groups tend to be more relationship oriented, whereas males' peer groups are more likely to be centered around a particular interest or activity. In both cases, group cohesion and a sense of belonging become important. Peers become increasingly important in middle adolescence, during which time the adolescent may experiment with being a part of different groups and “try on” different identities. These groups may include both sexes. Peer groups may arise from organized activities, such as sports or clubs, or may simply be friendship based. Gang membership is another form of peer acceptance. **Conformity** with the peers in manners of dress, speech, and behavior is a normal part of this process, and should not necessarily be viewed negatively. Similarly, **peer**

pressure may exist, but its influence over the adolescent's decision-making may be positive, negative, or negligible. Acceptance and successful navigation of peer groups during adolescence may give the individual more confidence to move into and out of various social, academic, and professional groups in the future. Late adolescents are less vulnerable to peer group influence, having moved closer to establishing their own stable identity. Their cognitive skills allow them to choose selectively among different peer groups, endorsing and adopting individual values and behaviors that best reflect who they are becoming.

Early adolescents have increased **sexual awareness and interest** , which may manifest as sexual talk and gossip, and often is focused on sexual anatomy. Masturbation and other sexual exploration, sometimes with same-sex peers, are common. The prevalence of other forms of sexual behavior varies by culture; in general, these behaviors are less common in early adolescents. Romantic relationships, if they exist at all, lack emotional depth. Sexual curiosity, experimentation, and activity become more common among middle adolescents. Same-sex attraction is common; sexual orientation may become clear to some adolescents, but still may be evolving in others during this time. Dating behaviors may be seen, but this is culture dependent and may not be a popular construct for all adolescents. Individual relationships often continue to emphasize sexual attraction over emotional intimacy; the latter may not be seen until late adolescence. At that time, relationships increasingly involve love and commitment and demonstrate greater stability.

Body image may affect (and be affected by) adolescents' psychosocial development as well. Early and middle adolescence are usually the ages at which poor or distorted body image and eating disorders develop. Early adolescents undergo rapid physical changes and may experience uncertainty about whether all these anatomic and physiologic changes are progressing normally. Reassurance from adults, including their healthcare providers, may be comforting. As puberty comes to an end and these changes slow, the middle adolescent's preoccupation may shift to whether the adolescent is attractive to others. A strong emphasis on physical appearance during this time is normal. Although this focus on physical appearance may continue into adulthood, late adolescence generally is characterized by a shifting balance toward introspection, with somewhat less emphasis placed on external characteristics.

The **timing of pubertal changes** also can affect psychosocial development and well-being. The progression of pubertal changes in males is generally associated with a positive self-image. Females may initially perceive these changes in their physical appearance more negatively. This appears to be especially true for early-maturing females, some of whom experience greater decreases in self-esteem, engage in more disruptive behaviors, and have more conflict with their parents than do on-time or late-maturing females. Perhaps because they are more comfortable associating with older peers, early-maturing females are vulnerable to making poor decisions when exposed to high-risk situations, still lacking the cognitive skills to effectively navigate these situations. Early-maturing males tend to have greater self-confidence, social, and academic success, while later-maturing males are at risk for more internalizing behaviors and diminished self-esteem. Many other factors influence how adolescents experience puberty, and supportive peers and adults can have a positive impact on psychosocial development. With successful navigation of these domains, emerging adults move into the world with a strong sense of personal identity and their place in society. They are able to work toward a vocation and financial independence and to manage the responsibilities of adulthood.

Implications for Providers, Parents, and Policymakers

Providers can help parents approach their child's adolescent years by reframing some of the “challenges” of adolescence as normal developmental milestones that should be anticipated and accepted. Puberty and emerging sexuality should be approached as positive and health-affirming life changes, rather than focusing discussions only on the negative reproductive risks and outcomes. Even good-natured teasing about bodily changes can be detrimental to the adolescent's self-image. Early-maturing females and late-maturing males should be supported, recognizing their potential increased risk for psychosocial challenges. Emerging positive coping strategies should be promoted in all youth, particularly those with chronic illness or other challenges. Providers need to determine the young adolescent's cognitive development and capacity for abstract thought and tailor their communication and counseling style accordingly. Physical examinations should be performed in private with the parent outside the exam room (provided the adolescent is comfortable with this), which also affords the adolescent and provider an opportunity to discuss confidential issues. Reassurance of normal development should be provided.

As adolescents develop more independence and parent–child conflict peaks, providers should remind parents that this is typical, and that arguing does not mean the adolescent does not value the parents' input and perspectives. Although some may rebel initially, most adolescents ultimately adopt a value system very similar to that of their parents. Even if discussions feel ineffective to parents, they should continue to demonstrate and model these values to their child. Similarly, rather than categorically dismissing their child's “negative” interests, such as playing a violent video game, parents should be encouraged to use these opportunities to model critical thinking about the impact of such an activity. Potentially negative peer groups may be approached the same way, while fostering the development of positive peer networks. **Authoritative parenting** , in which clear and appropriate negotiated limits are set in the context of a caring and mutually respectful parent–child relationship, is most strongly associated with positive psychosocial development. Parental connectedness and close supervision or monitoring of the youth's activities and peer group can be protective against early onset of sexual activity and involvement in other risk-taking behaviors and can foster positive youth development. Parents should also assume an active role in their adolescent's transition to adulthood to ensure that their child receives appropriate preventive health services.

Parents and providers may each work with adolescents to foster good decision-making. In addition to providing adolescents with accurate and complete health information, the adolescent's cognitive ability to use this information in various contexts must be considered. Adolescents may find themselves needing to make important decisions in highly charged situations where they may be unable to manage their emotions and use their higher cognitive functions to examine the consequences of their decision. For example, a couple in a sexual situation with high emotional arousal may make the decision to proceed with unprotected intercourse. By anticipating this situation ahead of time, under conditions of lower emotional arousal, and making a plan to deal with this, they may make a different decision (e.g., stick with their prior decision never to have sex without protection), when the time comes. Parents and healthcare providers are in a position to encourage and foster this anticipation and planning under conditions of “cool cognition.”

Providers may need to help parents distinguish normal adolescent development and risk-taking behaviors from possible signs of a more serious mental health or conduct problem. Bids for **autonomy** , such as avoiding family activities, demanding privacy, and increasing argumentativeness, are normal; extreme **withdrawal** or **antagonism** may be dysfunctional, signaling a mental health or substance use concern. Bewilderment and dysphoria at the start of middle school are normal; continued failure to adapt several months later suggests a more serious problem. Although some degree of risk taking is normal, progressive escalation of risk-taking behaviors is problematic. In general, when the adolescent's behaviors cause significant dysfunction in the domains of home life, academics, or peer relationships, they should be addressed by the parents and healthcare provider, and referral to a mental health provider may be considered. In most cases, parents can be reassured that although adolescence can pose unique challenges, their adolescent, like most adolescents, will come through it to become a successful and happy adult.

At national and international levels, adolescents are at risk for environmental, health, behavioral, and societal challenges. Table 132.4 provides suggestions to address these issues.

Table 132.4

Recommended Action Bundles* for Adolescent and Young Adult Health Problems and Risks

PROBLEM/RISK AREA	STRUCTURAL	SOCIAL MARKETING	COMMUNITY INTERVENTIONS INCLUDING FAMILY	ELECTRONIC HEALTH, MOBILE HEALTH	SCHOO
Sexual and reproductive health, including HIV	**Legislation** *18 years as the minimum age of marriage* *Allow provision of contraception to legal minors* *Legalize abortion*	*Promote community support for sexual and reproductive health, and HIV health access for adolescents*	**Cash transfer programs, with payments linked to staying in school** *Positive youth development* *Peer education*	*Target knowledge, attitudes, and risk behaviors*	**Qual** **secon** **educa** **Com** **sexua** **educa** **Safe** **with** **toilet** **facili** **mens** **Scho** **healt** **with** **and r** **contr**

CHAPTER 133

Gender and Sexual Identity

Walter O. Bockting

Terms and Definitions

Sex and Sexual Identity

Sex is multifaceted, with at least 9 components: chromosomal sex, gonadal sex, fetal hormonal sex (prenatal hormones produced by the gonads), internal morphologic sex (internal genitalia), external morphologic sex (external genitalia), hypothalamic sex (sex of the brain), sex of assignment and rearing, pubertal hormonal sex, and gender identity and role. **Sexual identity** is a self-perceived identification distilled from any or all aspects of sexuality and has at least 4 components: sex assigned at birth, gender identity, gender expression, and sexual orientation.

Sex Assigned at Birth

A newborn is assigned a sex before (typically through ultrasound) or at birth based on the external genitalia (natal sex). In case of a *disorder of sex development (intersex)* , these genitalia may appear ambiguous, and additional components of sex (e.g., chromosomal, gonadal, hormonal sex) are assessed. In consultation with specialists, parents assign the child a sex that they believe is most likely to be consistent with gender identity, which cannot be assessed until later in life (see Chapter 606).

Gender Terms

Gender identity refers to a person's basic sense of being a boy/man, girl/woman, or other gender (e.g., transgender, genderqueer, nonbinary, gender fluid). **Gender role** refers to one's role in society, typically the male or female role. Gender identity needs to be distinguished from **gender expression** , which refers to characteristics in personality, appearance, and behavior that are, in a given culture and time, considered masculine or feminine. Gender role is about one's presentation as a boy/man or girl/woman, whereas gender expression is about the masculine and/or feminine characteristics one exhibits in a given gender role. Both boys/men, girls/women, and transgender, genderqueer, or nonbinary persons can be masculine and/or feminine to varying degrees; gender identity and gender expression are not necessarily congruent. A child or adolescent might be **gender nonconforming** , that is, a predominantly feminine boy or a predominantly masculine girl.

Sexual Orientation and Behavior

Sexual orientation refers to attractions, behaviors, fantasies, and emotional attachments toward men, women, or both. **Sexual behavior** refers to any sensual activity to pleasure oneself or another person sexually.

Transgender

Transgender people are a diverse group of individuals whose gender identity differs from their sex assigned at birth. They include **transsexuals** (usually referred to as transgender) (who typically live in the other gender role and seek hormonal and/or surgical interventions to modify primary or secondary sex characteristics); **cross-dressers** (who wear clothing and adopt behaviors associated with the other sex for emotional or sexual gratification and may spend part of the time in the other gender role); **drag queens** and **kings** (female and male impersonators); and individuals identifying as **genderqueer** (differently gendered), **nonbinary** (neither male nor female, both, or in-between), or **gender fluid** (not fixed but changing). Transgender individuals may be attracted to men, women, or other transgender persons.

Factors That Influence Sexual Identity Development

During prenatal sexual development, a gene located on the Y chromosome (*XRY*

) induces the development of testes. The hormones produced by the testes direct sexual differentiation in the male direction resulting in the development of male internal and external genitalia. In the absence of this gene in XX chromosomal females, ovaries develop and sexual differentiation proceeds in the female direction, resulting in female internal and external genitalia. These hormones may also play a role in sexual differentiation of the brain. In disorders of sex development, chromosomal and prenatal hormonal sex varies from this typical developmental pattern and may result in ambiguous genitalia at birth.

Gender identity develops early in life and is typically fixed by 2-3 yr of age. Children first learn to identify their own and others' sex (**gender labeling**), then learn that gender is most often stable over time (**gender constancy**), and finally learn that gender is typically permanent (**gender consistency**). What determines gender identity remains largely unknown, but it is thought to be an interaction of biologic, environmental, and sociocultural factors.

Some evidence shows the impact of biologic and environmental factors on gender expression, whereas their impact on gender identity remains less clear. Animal research shows the influence of prenatal hormones on sexual differentiation of the brain. In humans, prenatal exposure to unusually high levels of androgens in girls with **congenital adrenal hyperplasia** is associated with more masculine gender expression, transgender identity, and same-sex sexual orientation, but cannot account for all the variance found (see Chapter 594). Research on environmental factors has focused on the influence of sex-typed socialization. Gender-based stereotypes develop early in life. Until later in adolescence, boys and girls are typically socially segregated by gender, reinforcing sex-typed characteristics such as boys' focus on “rough-and-tumble play” and asserting dominance, and girls focus on verbal communication and creating relationships. Parents, other adults, teachers, peers, and the media serve as gender-socializing role models and agents by treating boys and girls differently.

For information on the development of sexual orientation, see Chapter 134 .

Nonconformity in Gender Expression Among Children and Adolescents

Prevalence

Nonconformity in gender expression needs to be distinguished from a transgender identity. The former operates on the level of personality, appearance, and behavior (masculinity, femininity), whereas the latter is about self-perceived, core gender identity. Nonconformity in gender expression is more common among girls (7%) than boys (5%), but boys are referred more often than girls for concerns regarding gender identity and expression. This is likely a result of parents, teachers, and peers being less tolerant of gender nonconformity in boys than in girls.

Nonconformity in gender expression as part of exploring one's gender identity and role is part of normal sexual development. Gender nonconformity in childhood may or may not persist into adolescence. Marked gender nonconformity in adolescence often persists into adulthood. Only a minority of gender-nonconforming children develop an adult transgender identity; most develop a gay or lesbian identity, and some, a heterosexual identity.

Etiology of Gender-Nonconforming Behavior

Prenatal hormones play a role in the development of nonconformity in gender expression, but cannot completely account for all the variance. A heritable component of gender-nonconforming behavior likely exists, but twin studies indicate that genetic factors also do not account for all of the variance. Family-of-origin factors hypothesized to play a role in the development of gender nonconformity lack empirical support. Maternal psychopathology and emotional absence of the father are the only possible factors associated with gender nonconformity, yet it is unclear whether these factors are cause or effect.

Stigma, Stigma Management, and Advocacy

Gender nonconforming children are subject to **ostracism** and **bullying** (see Chapter 14.1) from peers, which may negatively impact their psychosocial adjustment and lead to social isolation, loneliness, low self-esteem, depression, suicide, and behavioral problems. To assist children and families, individual stigma management strategies, as well as interventions to change the environment, can be offered. **Stigma management** might involve consultation with a health professional to provide support and education, normalizing gender-nonconforming behavior and encouraging the child and family to build on the child's strengths and interests to foster self-esteem. It might also involve making choices about certain preferences (e.g., a boy who likes to wear feminine attire) to limit these to times and environments that are more accepting. *Most health professionals agree that too much focus on curtailing gender-nonconforming behavior leads to increased shame and undermines the child's self-esteem.*

The health professional and family can also assist the child or adolescent to find others with similar interests (within and beyond the gender-related interests) to strengthen positive peer support. Equally important are interventions in school and society to raise awareness and promote accepting and positive attitudes, take a stand against bullying and abuse, and implement antibullying policies and initiatives. *Gay, lesbian, bisexual, transgender, and straight alliance groups are helpful in providing a haven for gender-nonconforming youth, as well as recognizing them as part of diversity to be respected and embraced within the school system.* Healthcare system level approaches are outlined in Table 133.1 .

Table 133.1

Systems-Level Principles Underlying Lesbian, Gay, Bisexual, Transgender, Questioning (LGBTQ) Youth-Friendly Services

PRINCIPLE	DEFINITION	EXAMPLES
Availability	The presence of healthcare providers with knowledge, competence, and experience working with young people and with people with current or possibly developing LGBTQ identities, feelings, and/or behavior	Providers from various disciplines (e.g., physicians, nonphysician healthcare professionals) provide care sensitive to the needs of LGBTQ youth. Quality of care is high, with LGBTQ youth (and when appropriate, their caregivers) universally receiving recommended screening and anticipatory guidance.
Accessibility	The relative ease with which LGBTQ youth can obtain care from an available provider	Clinical services are located near where LGBTQ youth live, study, work, or otherwise spend time. Clinical services are easily obtained, with expanded hours during evenings and weekends, same-day urgent bookings, drop-in visits, and allowances for late appointments. Technology (e.g., online patient portals, email, telemedicine) is increasingly used to improve access for youth.
Acceptability	The extent to which clinical services are culturally competent and developmentally appropriate for LGBTQ youth, and to which confidentiality is ensured and protected	The clinic has a policy affirming its inclusive services for LGBTQ, and the clinical environment has signs, stickers, and other statements showing it is LGBT-friendly. Health brochures and other reading materials are tailored to the needs of

		LGBTQ youth. Confidentiality is ensured and protected in every patient encounter, and healthcare providers spend time one-on-one with patients to elicit sensitive information.
Equity	The degree to which clinical care is friendly to *all* LGBTQ youth, regardless of race, ethnicity, language, ability to pay, housing status, and insurance status, among other factors	High-quality care is provided to all youth, regardless of whether they are lesbian, gay, bisexual, or transgender. Culturally competent care is provided to LGBTQ youth of color, and services are available for patients who are not native English speaking. Services are provided free-of-charge for uninsured LGBTQ youth.

Making health services adolescent friendly—developing national quality standards for adolescent friendly health services, Geneva, 2012, World Health Organization.

Transgender and Gender-Nonconforming Identities Among Children and Adolescents

Prevalence

Approximately 1% of parents of 4-11 yr old boys report that their son wished to be of the other sex, with 3.5% for 4-11 yr old girls. Only a minority of children's gender identity concerns persist into adolescence (20% in one study of boys). Persistence of gender identity concerns from adolescence into adulthood is higher; the majority identify as transgender in adulthood and may pursue **gender-affirming medical interventions** (i.e., hormone therapy, surgery). The prevalence of transgender adults in the United States is estimated at 1 : 200.

Etiology of Transgender or Gender-Nonconforming Identities

The etiology of transgender and gender-nonconforming identities remains unknown. Environmental and biologic factors are hypothesized to play a role in the development of a transgender or gender-nonconforming identity. Gender-nonconforming children seem to have more trouble than other children with basic cognitive concepts concerning their gender. They may experience emotional distance from their father. Whether these factors are cause or effect remains unclear.

Prenatal and perinatal hormones may influence sexual differentiation of the brain. Some girls with congenital adrenal hyperplasia develop a male gender identity, but most do not. The size of the sex-dimorphic central part of the bed nucleus of the stria terminalis in the hypothalamus of transgender women is smaller than in males and within the range of nontransgender women; the opposite is true for transgender men. This structure is regulated by hormones in animals, but in humans no evidence yet exists of a direct relationship between prenatal and perinatal hormones and the sexually dimorphic nature of this nucleus. In addition, differences have been shown between transgender men and women and nontransgender controls in white matter microstructure of the brain.

Clinical Presentation

Children and adolescents with a gender-nonconforming identity may experience 2 sources of stress: internal distress inherent to the incongruence between sex assigned at birth and gender identity (gender dysphoria) or distress associated with social stigma. The 1st source of distress is reflected in discomfort with the developing primary and secondary sex characteristics and the gender role assigned at birth. The 2nd source of distress relates to feeling different, not fitting in, peer ostracism, and social isolation, and may result in shame, low self-esteem, anxiety, or depression.

Boys with a gender-nonconforming identity may at an early age identify as a girl, expect to grow up female, or express the wish to do so. They may experience distress about being a boy and/or having a male body, prefer to urinate in a sitting position, and express a specific dislike of their male genitals and even want to cut off their genitals. They may dress up in girls' clothes as part of playing dress up or in private. Girls may identify as a boy and expect or wish to grow up male. They may experience distress about being a girl and/or having a female body, pretend to have a penis, or expect to grow one. Girls may express a dislike of feminine clothing and hairstyles. In early childhood, children may spontaneously express these concerns, but depending on the response of the social environment, these feelings may go underground and may be kept more private. The distress may intensify by the onset of puberty; the physical changes of puberty are described by many transgender adolescents and adults as “traumatic.” Boys and girls may also identify outside of the gender binary (e.g., as boygirl, girlboy, genderqueer, gender fluid) and describe their identity as neither male nor female, both male and female, in-between, or some other alternative gender different from their sex assigned at birth. Adopting a **nonbinary identity** may be part of identity exploration or constitute a gender identification that persists over time.

Gender-nonconforming children and transgender adolescents may struggle with a number of general behavior problems. Both boys and girls predominantly internalize (anxious and depressed) rather than externalize behavioral difficulties. Boys are more prone to anxiety, have more negative emotions and a higher stress response, and are rated lower in self-worth, social competence, and psychological well-being. Gender-nonconforming children have more peer relationship difficulties than controls. Both femininity in boys and masculinity in girls are socially stigmatized, although the former seems to carry a higher level of stigma. Boys have been shown to be teased more than girls; teasing for boys increases with age. *Poor peer relations* is the strongest predictor of behavior problems in both boys and girls.

Transgender adolescents may struggle with a number of adjustment problems as a result of social stigma and lack of access to gender-affirming healthcare. Transgender youth, especially those of ethnic/racial minority groups, are vulnerable to verbal and physical abuse, academic difficulties, school dropout, illicit hormone and silicone use, substance use, difficulty finding employment, homelessness, sex work, forced sex, incarceration, HIV/sexually transmitted infections (STIs), and suicide. Parental support can buffer against psychological distress, but many parents react negatively to their child's gender nonconformity, although mothers tend to be more supportive than fathers.

The Diagnosis of Gender Dysphoria: Criteria and Critique

Gender dysphoria (or **gender incongruence**) is classified as a mental disorder in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and *International Classification of Diseases* (ICD), which, particularly for children, is controversial (Table 133.2). Critics have argued that the distress children experience is mainly the result of social stigma rather than being inherent to gender nonconformity and thus should not be considered a mental disorder.

Critics have also expressed concern about children with normal variation in gender role being labeled with a mental disorder perpetuating social stigma, yet there is a tendency of clinicians to underdiagnose rather than overdiagnose children whose gender nonconformity goes beyond behavior and who report gender dysphoria. These children may benefit from the diagnosis to receive early treatment in the form of support, education, advocacy, and, in case of clinically significant distress, changes in gender role, **puberty suppression, and/or feminizing or masculinizing hormone therapy in adolescence** .

Table 133.2

Summary of DSM-5 Diagnostic Criteria for Gender Dysphoria

GENDER DYSPHORIA IN CHILDREN (302.6) (F64.2)

A. A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 mo duration, as manifested by at least 6 of the following (1 of which must be criterion A1):
    1. A strong desire to be of the other gender or an insistence that one is the other gender (or some alternative gender different from one's assigned gender).
    2. In boys (assigned gender), a strong preference for cross-dressing or simulating female attire; or in girls (assigned gender), a strong preference for wearing only typical masculine clothing and a strong resistance to the wearing of typical feminine clothing.
    3. A strong preferences for cross-gender roles in make-believe play or fantasy play.
    4. A strong preference for the toys, games, or activities stereotypically used or engaged in by the other gender.
    5. A strong preference for playmates of the other gender.
    6. In boys (assigned gender), a strong rejection of typically masculine toys, games, and activities and a strong avoidance of rough-and-tumble play; or in girls (assigned gender), a strong rejection of typically feminine toys, games, and activities.
    7. A strong dislike of one's sexual anatomy.
    8. A strong desire for the primary and/or secondary sex characteristics that match one's experienced gender.

B. The condition is associated with clinically significant distress or impairment in social, school, or other important areas of functioning.

SPECIFY IF WITH A DISORDER OF SEX DEVELOPMENT (E.G., CONGENITAL ADRENAL HYPERPLASIA OR ANDROGEN INSENSITIVITY SYNDROME)

GENDER DYSPHORIA IN ADOLESCENTS OR ADULTS

A. A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 mo duration, as manifested by at least 2 of the following:

1. A marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics).
2. A strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics).
3. A strong desire for the primary and/or secondary sex characteristics of the other gender.
4. A strong desire to be of the other gender (or some alternative gender different from one's assigned gender).
5. A strong desire to be treated as the other gender (or some alternative gender different from one's assigned gender).
6. A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's assigned gender).

B. The condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning.

SPECIFY IF WITH A DISORDER OF SEX DEVELOPMENT (E.G., CONGENITAL ADRENAL HYPERPLASIA OR ANDROGEN INSENSITIVITY SYNDROME)

SPECIFY IF POSTTRANSITION: The individual has transitioned to full-time living in the desired gender (with or without legalization of gender change) and has undergone (or is preparing to have) at least one cross-sex medical procedure or treatment regimen, namely, regular cross-sex hormone treatment or gender reassignment surgery confirming the desired gender (e.g., penectomy, vaginoplasty in a natal male; mastectomy or phalloplasty in a natal female).

Transgender Identity Development

A stages model of coming out might be helpful to understand the experience and potential challenges transgender youth might face. In the **pre–coming out** stage, the child or adolescent is aware that their gender identity is different from that of most boys and girls. In addition to a gender identity that varies from sex assigned at birth, some of these children are also nonconforming in gender expression while others are not. Those who are also nonconforming in gender expression cannot hide their transgender identity, are noticed for who they are, and may face teasing, ridicule, abuse, and rejection. They must learn to cope with these challenges at an early age and usually proceed quickly to the next stage of **coming out** . Children who are not visibly nonconforming in gender expression are able to avoid stigma and rejection by hiding their transgender feelings. They often experience a split between their gender identity cherished in private and expressed in fantasy and a false self presented outwardly to fit in and meet gendered expectations. These children and adolescents often proceed to coming out later in adolescence or adulthood.

Coming out involves acknowledging one's transgender identity to self and others (parents, other caregivers, trusted health providers, peers). An open and accepting attitude is essential; rejection can perpetuate stigma and its negative emotional consequences. By accessing transgender community resources, including peer support (either online or offline), transgender youth can then proceed to the **exploration** stage. This is a time of learning as much as possible about being transgender, getting to know similar others, and experimenting with various options for gender expression. Changes in gender role are carefully considered, as are medical interventions to delay puberty and/or feminize or masculinize the body to alleviate dysphoria. Successful resolution of this stage is a sense of pride in being transgender and comfort with gender role and expression.

Once gender dysphoria has been alleviated, youth can proceed with other human development tasks, including dating and relationships in the **intimacy** stage. As a result of social stigma and rejection, transgender youth may struggle with feeling unlovable. Sexual development has often been compromised by gender and genital dysphoria. Now that greater comfort has been achieved with gender identity and gender expression, dating and sexual intimacy have a greater chance of succeeding. Finally, in the **integration** stage, transgender is no longer the most important signifier of identity, but one of several important parts of overall identity.

Interventions and Treatment

Health providers can assist gender-nonconforming children, transgender adolescents, and their families by directing them to resources and by helping them to make informed decisions about changes in gender role and the available medical interventions to reduce intense and persistent gender dysphoria. To alleviate socially induced distress, interventions focus on stigma management and stigma reduction. It might be in the child's best interest to set reasonable limits on gender expression contributing to teasing and ridicule. The main goal of these interventions is not to change the child's gender-nonconforming behavior but to assist families, schools, and the wider community to create a supportive environment where the child can thrive and safely explore his or her gender identity and expression. Decisions to change gender roles, particularly in school, are not to be taken lightly and are best carefully anticipated and planned in consultation with parents, child, teachers, school counselor, and other providers involved in the adolescent's care. Medical interventions are available as early as Tanner Stage 2. Such treatment is guided by the Standards of Care set forth by the **World Professional Association for Transgender Health** (WPATH). Although some controversy still exists about the appropriateness of early medical intervention, follow-up studies of adolescents treated in accordance with these guidelines show its effectiveness in alleviating intense and persistent gender dysphoria.

Pubertal suppression with gonadotrophin-releasing hormone analogues (usually begun in early puberty) that delay puberty are helpful before gender-affirmation hormone therapies. Certain features of puberty are difficult to reverse (e.g., male facies, Adam's apple), so pubertal suppression avoids these physical features. Pubertal suppression may also reduce gender dysphoria. Gender-affirming hormones can then be initiated; testosterone for masculinizing and estrogen plus an adrogen inhibitor for feminization. Gender-affirming surgery (most commonly "top" surgery) to create a male-typical chest is usually delayed until adulthood.

Pediatricians who encounter transgender youth in their practice should be careful not to make assumptions about gender and sexual identity, but rather ask youth how they would describe themselves. This includes asking if they like being a boy or girl, have ever questioned this, wished they were born the other sex, or define their gender identity in a nonbinary or otherwise different way; and if they have a preferred nickname or pronoun (*he/him* , *she/her,* or *they/them;* if not sure, avoid pronouns). It also includes asking how they feel about their maturing body and sex characteristics, and what they would change about that if they could. Extra caution should be exercised during physical and genital exams because transgender youth may be particularly uncomfortable with their anatomy. When considering contraceptive options for female-to-male transgender youth, alternatives to feminizing agents should be explored. *For gender-affirming medical interventions, transgender youth should be referred to specialists in the treatment of gender dysphoria* (see www.wpath.org). For other health concerns, ensure referral to transgender or lesbian, gay, bisexual, transgender (LGBT)-friendly providers, especially in the case of gender-segregated treatment facilities. **Gender Spectrum** (www.genderspectrum.org), **Advocates for Youth** (www.advocatesforyouth.org), and **Parents, Families and Friends of Lesbians and Gays** (www.pflag.org) offer excellent support resources for transgender youth and their families.

CHAPTER 134

Gay, Lesbian, and Bisexual Adolescents

Stewart L. Adelson, Mark A. Schuster

Understanding a child's or adolescent's sexual and emotional development is an essential part of any comprehensive pediatric evaluation. For youth who are or might be gay, lesbian, or bisexual (**GLB**), such understanding is particularly important. GLB youth as a group have the same health and developmental needs as all youth, and their sexual orientation is part of the spectrum of human sexuality. However, they encounter distinct developmental challenges and can have additional physical and mental health needs related to their orientation and others' reaction to it. Their sexual orientation is often different from that expected by family, peers, and society (although expectations have been changing in many contexts), and they must cope with peer rejection, bullying, or family nonacceptance more frequently than most youth. Although the majority of GLB adolescents grow up physically and mentally healthy, they are at increased risk for certain health problems as a result of these stresses and the epidemiology of health threats such as HIV and other sexually transmitted infections (STIs). Pediatric clinicians are key in monitoring for such issues, supporting healthy development, and intervening when necessary to prevent or treat the problems for which GLB youth are at increased risk.

Sexual orientation refers to an individual's attraction to others based on sex or gender. It encompasses emotional and erotic desires, physiologic arousal, sexual behavior, sexual identity, and social role. As sexuality develops, youth can be oriented entirely toward a particular sex or gender, or more than one, to various degrees on a continuum. **Homosexuality** involves orientation toward people of one's same sex or gender, and **bisexuality** involves orientation toward males and females. **Gay** is a common term for homosexual males and females; **lesbian** refers to homosexual females. Some do not fit these categories and use other terms to describe themselves. Those unsure of their orientation are **curious** or **questioning** . The term **young men who have sex with men** (**YMSM**) is sometimes used in the research literature to denote male youth who engage in sexual activity with other males, regardless of how they identify themselves.

Prevalence of Homosexuality and Bisexuality in Youth

Some junior high and high school students self-identify as gay, lesbian, or bisexual. Some who do not identify as GLB report same-sex attraction, fantasies, or behavior. Some are unsure of their sexual orientation. Certainty about sexual orientation tends to increase through adolescence with sexual experience, although one can be aware of one's orientation without having had sexual partners. Those who fear nonacceptance may try to suppress or deny their orientation. Consequently, various aspects of orientation—attraction, behavior, and identity—may not be consistent in an individual and may change during development. Not all youth with homosexual attraction or experience identify as "gay," consistent in part with reluctance about having or revealing a gay identity and underscoring the differences among attraction, behavior, and identity. A report providing national estimates of the number of high school students with GLB identity in 2015 found that across 25 states and 19 large urban school districts, a median of 2.7% said they were gay/lesbian, 6.4% said they were bisexual, and 4.0% reported being unsure of their sexual orientation.

Development of Sexual Orientation in Childhood and Adolescence

Sexual orientation development appears to begin prenatally and continue through childhood and adolescence and into adulthood. Both gender role behavior in childhood and sexual orientation in puberty and adolescence are partly influenced by prenatal genetic and neuroendocrine factors. Sociocultural and psychological factors also influence sexual development. A gay or lesbian sexual orientation is sometimes preceded developmentally in childhood by **nonconforming gender expression** , or variation from population averages in expression of **gender-related behavior** such as activities, interests, styles, and other attributes recognized as masculine or feminine, such as toy preferences and preference for playmates of a particular gender. Although childhood gender nonconformity is not experienced by all gay or lesbian people—and not all children with nonconforming gender role behavior grow up to be gay or lesbian—nonconformity is not uncommon (particularly among males) and leads many gay or lesbian people to feel different from peers in childhood, even before sexual desire or identity emerges. Depending on the setting, gender-nonconforming children may experience ostracism, bullying, or family nonacceptance. These reactions to gender nonconformity can lead to later difficulty with gender-related self-esteem and long-term mental health problems.

Less frequently, gay or lesbian sexual orientation in adolescence is preceded by childhood **gender variant identity** , a phenomenon in which the gender identity of an individual at any age differs from phenotypic sex and assigned sex at birth (see Chapter 135).

Stigma, Risk, and Resilience

Homosexuality has been documented across cultures and historical periods. However, its meaning and acceptance vary greatly with social context. Although gay people are now generally more visible and accepted than previously, youth are often exposed to antihomosexual attitudes. For many GLB youth, revealing their sexual orientation (“coming out”) to family, peers, healthcare providers, and others is a significant step. Specific racial/ethnic, religious, and other demographic groups may experience distinct developmental stressors. For example, black youth report feeling less comfortable than white peers with a gay identity and less comfortable disclosing it.

Some GLB youth experience difficulty coping with **stigma** . A longitudinal study that investigated **bullying** and **victimization** among youth from 5th through 10th grade found that the girls and boys that identified as GLB in 10th grade were more likely than their peers to report that they had been bullied and victimized across grades. GLB youth may be perceived by others as different before they themselves have any GLB attraction or experience, or identify as GLB. Even when not overtly threatened, GLB youth frequently encounter negative attitudes that force them to hide at a time when acceptance holds great developmental significance. Family nonacceptance, feeling unsafe due to school harassment, and peer bullying related to sexual orientation elevate risk in GLB adolescents for depression, anxiety, substance abuse, suicidal thoughts and attempts, and social problems such as truancy, dropping out, running away, and homelessness. Mental health problems, sexual risk taking, or substance use may increase exposure to HIV and other STIs. Stigma may also impede access to healthcare in some communities. Thus, along with factors influencing exposure and susceptibility to health threats, stigma partly mediates elevated risk for health and mental health problems in GLB youth.

Nevertheless, most GLB youth are resilient, with good physical and mental health despite pervasive stress. Family connectedness and school support and safety are important protective factors against depression, suicidal thoughts and attempts, and substance abuse. GLB antiharassment policies and organizations such as **genders and sexualities alliances** (also sometimes called gay-straight alliances) and antibullying programs are associated with increased school safety for GLB youth. It is therefore important to reduce stigma, support acceptance, and promote resilient coping.

Health

Depression and Suicidality

Compared to their heterosexual peers, GLB youth and those who are not sure of their sexual orientation have higher prevalence of suicidality. Family rejection, bullying, and other victimization motivated by homophobia account statistically for increased depression and suicidal thoughts and attempts in GLB adolescents. Suicidal thoughts or attempts are highest during the interval following recognition of same-sex attraction or a same-sex sexual experience but prior to self-acceptance as gay.

Sexually Transmitted Infections

The epidemiology of STIs, related to specific sexual practices as well as prevalence of certain STIs in GLB communities, informs recommended counseling, screening, and treatment strategies. Anal intercourse has been shown to be the most efficient route of infection by hepatitis B (Chapter 385), cytomegalovirus (Chapter 282), and HIV (Chapter 302). Oral-anal and digital-anal contact can transmit enteric pathogens, such as hepatitis A. Unprotected oral sex also can lead to oropharyngeal disease in the receptive partner and gonococcal and nongonococcal urethritis in the insertive partner. Certain STIs, particularly ulcerative diseases, such as syphilis and herpes simplex virus infection, facilitate spread of HIV.

Among U.S. adolescents and young adults, YMSM, and especially black YMSM, continue to face the greatest prevalence of HIV/AIDS. Although possible, female-to-female sexual transmission of HIV is inefficient, and females who only engage in sex with females are less likely than other youth to acquire an STI. However, boys and girls who identify as gay or lesbian may engage in sexual activity with partners of the other sex, so counseling and screening for all types of STIs are still relevant.

Substance Abuse

Compared with their heterosexual peers, GLB youth appear to use alcohol and other substances at higher rates, including more binge drinking and earlier onset and more rapid trajectory of substance use. More substantial substance use may be greatest in youth who do not identify as GLB but have same-sex attractions or engage in same-sex sexual behavior.

Obesity and Disordered Eating

Compared with heterosexual girls, lesbian and bisexual girls are generally more likely to be obese or overweight. In contrast, young gay and bisexual males are more likely to have body image concerns and to restrict eating or engage in compensatory weight loss strategies compared to heterosexual boys. Binge eating may also be more common in GLB youth.

Psychosocial Problems

Academic underachievement, truancy, and dropping out of school are frequently associated in GLB adolescents with homophobic victimization, harassment, violence, and feeling unsafe at school. Studies suggest that youth who eventually identify as GLB have higher rates than other youth of experiencing child abuse and of running away or being kicked out of their homes. GLB young people are overrepresented among homeless and runaway populations across the United States, which can expose them to drugs, sexual abuse and other health risks.

Recommendations for Care

Evaluation

The goal of GLB pediatric care is physical health, social and emotional well-being, and healthy development. Physicians should provide nonjudgmental care to all adolescents, including those who are GLB or questioning (see Chapter 133 , Table 133.1). They should receive the age-appropriate history, examination, and anticipatory guidance recommended for adolescents in general. With some exceptions noted later, the physical examination and laboratory evaluation of GLB and questioning adolescents are the same as for any teenager. However, providers should appropriately screen for special potential medical and psychosocial threats to GLB teenagers' health.

A nonjudgmental healthcare environment is important, with open communication and a positive relationship with youth and families. In the waiting room, written material about sexual orientation, support groups, and community resources will signal openness to discussing sexuality. Registration forms recognizing the possibility of same-gender parents signal a safe setting (e.g., forms can list parent/guardian #1, parent/guardian #2). Sexual history questions should avoid heterosexual assumptions (e.g., "Are you dating someone?" vs "Do you have a boyfriend/girlfriend?"). This is important at all ages. For example, asking a 6 yr old boy if he has a girlfriend may convey an unsupportive message if he discovers later that he would like a boyfriend. Explaining confidentiality and incorporating into each adolescent visit private time with no parent in the room (see Chapter 137) may facilitate discussing sexual orientation, as may use of appropriate health history forms such as the American Medical Association's Guidelines for Adolescent Prevention Services Questionnaire.

Clinicians should remember that any youth might be GLB whether or not they are identified or perceived as such, so clinicians should not presuppose a particular orientation. Competency in conveying sensitivity, acceptance, and respectfulness; effective communication skills; and appropriate attention to privacy and confidentiality (including practices related to billing and record requests) are fundamental to providing high-quality care. While remaining attuned to youth's preferences, explicit or implied, for discussing sexual orientation, providers can tactfully take the lead, if necessary, regarding any pressing areas of clinical concern.

Medical and Sexual Health

STIs are covered in Chapter 146 , but issues specific to GLB youth are included here. Use of latex condoms for fellatio, and dental dams and cut-open latex condoms for anilingus and cunnilingus, should be discussed with adolescents. Recommendations also include use of latex condoms for sexual appliances. In addition, it is important to emphasize that people who have been using alcohol or other drugs are at increased likelihood for engaging in riskier sexual activity. It is important not to assume that a gay boy or lesbian girl who does not identify as bisexual has not had sex with someone of a different sex or gender. For example, lesbians can still have an unplanned pregnancy. Therefore, prevention counseling about unintended pregnancy is relevant to all adolescents. Similarly, youth who identify as heterosexual and whose attractions are not to those of the same sex or gender may still have sexual activity with a partner of the same sex or gender.

Although vaccination against hepatitis A and B is recommended for all children, it is particularly recommended that nonvaccinated adolescent males who are having sex or are likely to have sex with males receive catch-up vaccines. The same recommendation applies to the human papillomavirus (HPV) vaccine for males. The Centers for Disease Control and Prevention (CDC) recommends that males who are engaging in sexual activity with males have annual testing for HIV, hepatitis A, hepatitis B, syphilis, urethral gonorrhea and chlamydia (if engaging in insertive oral or anal intercourse), oral gonorrhea (if engaging in receptive oral intercourse), and rectal gonorrhea and chlamydia (if engaging in receptive anal intercourse).

Mental Health

Awareness of mental health and social problems is important when caring for GLB youth, as for all youth. Clinicians should monitor for depression, suicidality, anxiety, and substance abuse and know their community's mental health resources. Minor psychosocial problems might be handled by referral to a support group for patients (e.g., GLSEN, formerly known as the Gay, Lesbian and Straight Education Network) or for parents and others (e.g., Parents, Families and Friends of Lesbians and Gays). In some communities, agencies and organizations serving the GLB community can help with social, educational, vocational, housing, and other needs.

Individuals or families who harbor negative attitudes may inquire about mental health treatment to avert or change a homosexual or bisexual orientation. However, a GLB orientation is not an illness, and leading health organizations, including the American Academy of Pediatrics, American Academy of Family Physicians, Society for Adolescent Health and Medicine, American Academy of Child and Adolescent Psychiatry, and American Medical Association, have concluded that such change is neither possible nor warranted. It is important to distinguish between a GLB orientation, which is not a mental illness, and mental health problems (e.g., depression) for which GLB youth are at elevated risk. While understanding different families' values, clinicians must recognize the morbidity and mortality associated with stigma and attempt to foster physical and emotional health. Individual or family therapy might be indicated.

Clinicians should also monitor for specific stressors, such as bullying and other homophobic victimization, family nonacceptance, and abuse. Failure to confront harassment constitutes tacit assent.

Anticipatory guidance, referral, and substance abuse treatment should be considered for the subset of GLB youth who use alcohol, drugs, or tobacco, some of whom may be using these to manage painful feelings related to conflicts over their sexuality.

Adolescents with serious psychiatric symptoms, such as suicidality, depression, and substance abuse, should be referred to mental health specialists with competency in treating GLB adolescents. It is essential to know how to recognize and manage psychiatric emergencies such as suicidal thoughts and attempts (see Chapter 40).

CHAPTER 135

Transgender Care

Walter O. Bockting

Transgender individuals have a gender identity that differs significantly from the sex they were assigned at birth (see Chapter 133). They may experience **gender dysphoria** , defined as clinically significant distress or impairment in social, school/occupational, or other important areas of functioning associated with incongruence between one's experienced/expressed gender and assigned gender, for at least 6 mo in duration. **Gender-affirming care** has been shown to alleviate gender dysphoria and may include psychological evaluation and supportive therapy, puberty suppression, feminizing or masculinizing hormone therapy, and surgery. Such care is guided by the Standards of Care for **transsexual** , **transgender** , and **gender-nonconforming** people set forth by the World Professional Association for Transgender Health (WPATH). In addition, the Endocrine Society has issued practice guidelines for endocrine treatment to alleviate gender dysphoria.

Transgender and gender-nonconforming children and adolescents have increased vulnerability to mental health concerns because of social stigma attached to gender nonconformity. Moreover, transgender and gender-nonconforming children and adolescents may present with general health concerns unrelated to their gender identity or gender expression, but may experience barriers to care that include a lack of cultural competence on the part of healthcare providers or the healthcare systems in which they practice. Therefore, to serve the youth and their families adequately, attention to both cultural and clinical competency is critical and should be improved. The American Psychological Association and the American Association of Child and Adolescent Psychiatrists have published practice guidelines to promote improved access to competent care.

Cultural and Clinical Competence

Cultural competence refers to the ability to communicate effectively with patients from various backgrounds. This includes appropriate assessment and clinical documentation of both gender identity (What is your current gender identity?) and sex assigned at birth (What sex were you assigned at birth [on your original birth certificate]?), use of preferred names and pronouns, and availability of all-gender bathrooms. It also includes recognition of and respect for gender diversity: children and adolescents may identify as girl, boy, boygirl, girlboy, transgender, genderqueer, nonbinary, gender fluid, gender questioning, or any other way in which they may describe their gender identity and expression (see Chapter 133). Particularly with children and adolescents, it is imperative not to label prematurely a young person's gender identity, but rather allow ample time for them to explore their gender identity and expression.

Clinical competence in transgender care refers to training and experience in providing gender-affirming care to facilitate gender identity development, alleviate any gender dysphoria, and promote resilience in the face of stigma. Care should ideally be provided by an interdisciplinary team or, alternatively, in consultation with other providers involved in the child or adolescent's care. This may include primary care providers, pediatric endocrinologists, and mental health professionals. The WPATH Standards of Care recommend that providers be competent in working with children and adolescents; be able to screen for coexisting mental health concerns; be knowledgeable about gender-nonconforming identities and expressions; and be knowledgeable and engaged in continuing education about the assessment and treatment of gender dysphoria.

Gender Literacy

For both providers and patients (child or adolescent and family), an up-to-date understanding of gender diversity is key. Much is yet to be learned about transgender identity development, but we do know that gender is not necessarily *binary,* and transgender and gender-nonconforming children and adolescents may identify and express their gender identity along a spectrum. The implication for care is that not all these children and adolescents need to change their gender role from male to female or female to male, and are in need of early medical interventions. Certainly, for some transgender and gender-nonconforming children and adolescents, these interventions are medically necessary and lifesaving, and evidence to date indicates that for those who meet criteria for a DSM-5 diagnosis of gender dysphoria, treatment appears safe and effective in reducing gender dysphoria and optimizing mental health and well-being. Others, however, do not identify with the gender binary (i.e., do not identify as male or female, but rather as an alternative gender) and need a more individualized approach that may or may not include changes in gender role and/or any of the available medical interventions. For all young people, it is imperative to support them in the process of identity exploration and tolerate any ambiguity and uncertainty, as well as evaluate and treat their concerns in light of their overall child and adolescent development.

Assessment

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) outlines criteria for a diagnosis of gender dysphoria in children as well as in adolescents and adults (see Table 133.2). For children, these criteria must include a strong desire or insistence to be of the other gender (or some alternative gender that differs from one's assigned gender). For adolescents, this may include a marked incongruence between one's experienced/expressed gender and (anticipated) primary and/or secondary sex characteristics; a strong desire for the sex characteristics of the other gender (or some alternative gender that differs from one's assigned gender), and/or a strong desire to be treated as another gender.

There is considerable variation in the clinical presentation, severity, and persistence of gender dysphoria among children and adolescents. It is therefore important to obtain a history of gender identification and expression and monitor ongoing identity exploration and development. Coexisting mental health concerns of anxiety, depression, nonsuicidal self-injury, suicidal ideation, and suicide attempts are not uncommon and should be assessed. There also is a higher prevalence of autism spectrum disorder among children and adolescents presenting with gender dysphoria.

Treatment

Transgender and gender-nonconforming children and adolescents can benefit greatly from a nonjudgmental and empathetic stance, patient education about gender diversity and the available options to alleviate gender dysphoria and affirm gender identity, access to community resources, and family support. Attention to behavioral problems and therapy for any mental health concerns caused by gender nonconformity and the attached social stigma should be incorporated into the treatment plan.

Treatment of gender dysphoria may include psychotherapy to reduce distress related to gender dysphoria or any other psychosocial difficulties. *Gender nonconformity in and of itself is not pathologic.* In addition, it is not ethical to try to change gender identity and expression to become more congruent with sex assigned at birth, because this has proved unsuccessful, particularly in the long term. Instead, psychotherapy (by a professional trained in transgender health) should support the unfolding process of identity exploration and development and assist the patient and family to manage any uncertainty and anxiety about the eventual outcome. Options to affirm gender identity include changes in gender role and expression, puberty suppression, feminizing or masculinizing hormones, and surgery. Changes in gender role may include changes in name and pronouns.

Puberty suppression with GnRH analogs, a reversible early medical intervention to reduce dysphoria by preventing the development of unwanted sex characteristics, is available as early as Tanner Stage 2. Feminizing or masculinizing **hormone therapy** , only partially reversible, is available and should be tailored to the somatic, emotional, and mental development of the adolescent. **Masculinizing chest surgery** , irreversible, is available preferably after ample experience living in a gender role congruent with the adolescent's gender identity. **Breast augmentation** is available, particularly after feminizing hormones have reached their maximum impact on breast growth. Hormone therapy or chest/breast surgery is indicated in patients with persistent, well-documented gender dysphoria who have the capacity to make a fully informed decision and to consent for treatment. **Genital surgery** (phalloplasty, metoidioplasty, vaginoplasty), irreversible, is available after living for a least 12 mo in a gender role congruent with the adolescent's gender identity, and preferably after the legal age of majority to give consent for medical procedures has been reached. For all these options, informed consent and support from family are critically important.

Early medical interventions have shown great promise in reducing gender dysphoria and optimizing psychosocial adjustment and well-being, but much remains unknown, particularly about the long-term effects of puberty suppression. Moreover, gender identity and expression should be evaluated within the larger context of identity and human development, especially during the formative years of childhood and adolescence.

Many transgender people choose hormone therapy and do not undergo surgery of breast/chest or genitals. The implications for fertility and options for fertility preservation should be discussed and considered before hormone therapy and surgery. Indeed, there are transgender individuals who elect to have children and nurse the child after birth. Rather than using the term *breastfeeding* , the term *chest feeding* may be preferred. When transgender adults seek primary healthcare, attention must be focused on gender- as well as sex organ–specific preventive screening (e.g., Pap smear, mammography, prostate exam).

Families

Family support is an important resource for transgender and gender-nonconforming youth and has been shown to buffer the negative impact of stigma on mental health. Family support also is a prerequisite for initiation of puberty suppression, feminizing or masculinizing hormone therapy, or any surgery before the age of legal majority has been reached. Providers are encouraged to include family in all aspects of treatment, while understanding that family members may be at different points in the process of coming to terms with having a transgender or gender-nonconforming loved one. Family members may benefit from online and community resources to educate themselves about gender diversity and to connect with similar others. Transgender and gender-nonconforming children and adolescents as well as their families are encouraged to learn as much as possible to be able to make fully informed decisions, in consultation with clinically competent transgender care providers, about the available behavioral and medical treatment options to affirm gender identity.

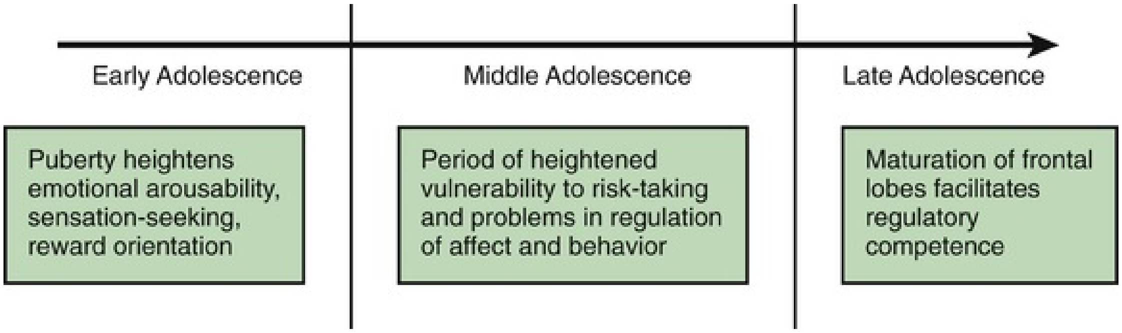
CHAPTER 136

The Epidemiology of Adolescent Health Problems

Gale R. Burstein

Adolescence is the first period of life where the major determinants of morbidity and mortality are *behavioral* rather than congenital or infectious. As adolescents make the transition from childhood to adulthood, they establish **behaviors** that affect both their current and future health. Adolescence is a time of immense **biologic, psychological, and social change** (see Chapter 132). Many of the psychological changes have a biologic substrate in the development and eventual maturation of the central nervous system, particularly the frontal lobe areas responsible for executive functioning (Fig. 136.1). In addition to cognitive development, there are both risk and protective factors for adverse adolescent health behaviors that are dependent on the social environment as well as the mental health of an adolescent (Table 136.1).



Early Adolescence
Middle Adolescence
Late Adolescence
Puberty heightens emotional arousability, sensation-seeking, reward orientation
Period of heightened vulnerability to risk-taking and problems in regulation of affect and behavior
Maturation of frontal lobes facilitates regulatory competence

FIG. 136.1 It has been speculated that the impact of puberty on arousal and motivation occurs before the maturation of the frontal lobes is complete. This gap may create a period of heightened vulnerability to problems in the regulation of affect and behavior, which might help to explain the increased potential in adolescence for risk taking, recklessness, and the onset of emotional and behavioral problems. (From Steinberg L:

Cognitive and affective development in adolescence, *Trends Cogn Sci* 9:69–74, 2005.)

Table 136.1

Identified Risk and Protective Factors for Adolescent Health Behaviors

BEHAVIOR	RISK FACTORS	PROTECTIVE FACTORS
Smoking	Depression and other mental health problems, alcohol use, disconnectedness from school or family, difficulty talking with parents, minority ethnicity, low school achievement, peer smoking	Family connectedness, perceived healthiness, higher parental expectations, low prevalence of smoking in school
Alcohol and drug misuse	Depression and other mental health problems, low self-esteem, easy family access to alcohol, working outside school, difficulty talking with parents, risk factors for transition from occasional to regular substance misuse (smoking, availability of substances, peer use, other risk behaviors)	Connectedness with school and family, religious affiliation
Teenage pregnancy	Deprivation, city residence, low educational expectations, lack of access to sexual health services, drug and alcohol use	Connectedness with school and family, religious affiliation
Sexually transmitted infections	Mental health problems, substance misuse	Connectedness with school and family, religious affiliation

Adapted from McIntiosh N, Helms P, Smyth R, editors. *Fofar and Arneil's textbook of pediatrics,* ed 6, Edinburgh, 2003, Churchill Livingstone, pp 1757–1768; and Viner R, Macfarlane A: Health promotion, *BMJ* 330:527–529, 2005.

Many adolescents continually confront the task of making healthy choices while struggling with impulsivity that can lead to unintentional consequences, such as injuries, sexually transmitted infections (STIs), or drug overdoses. Adolescents are also challenged with adopting behaviors that will affect their future adult health, such as eating nutritiously, engaging in physical activity, and choosing not to use tobacco. Environmental factors, such as family, peers, school, community, and religiosity, also contribute to adolescents' health and risk behaviors. The U.S. Centers for Disease Control and Prevention (CDC) **Youth Risk Behavior Surveillance Survey** , a school-based survey of a nationally representative sample of U.S. high school students, demonstrates that youth begin engaging in behaviors that place their health at risk during adolescence (Fig. 136.2).

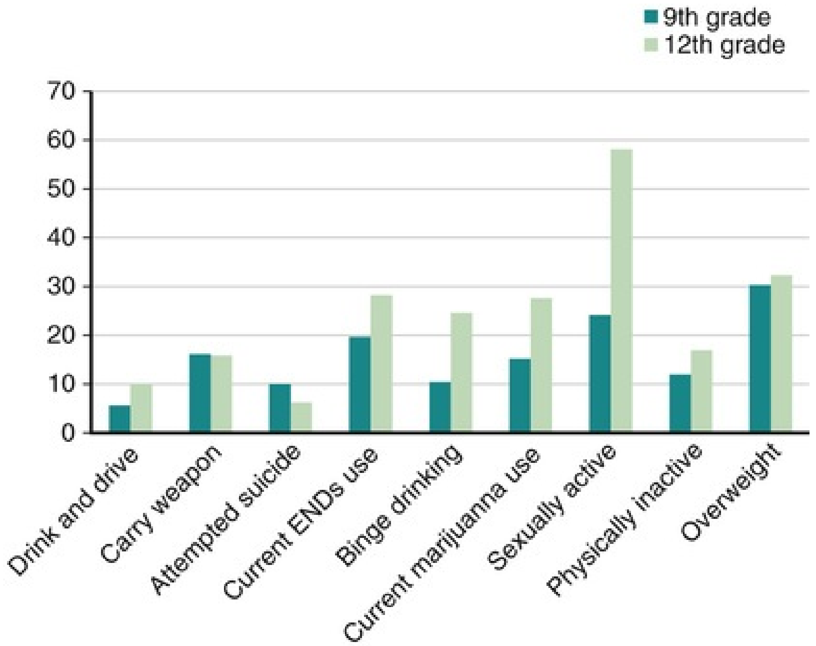


FIG. 136.2 Selected health behaviors among 9th and 12th grade high school students. ENDs, Electronic nicotine delivery system. (Data from Centers for Disease Control and Prevention: 1991–2015 High school youth risk behavior survey data. http://nccd.cdc.gov/youthonline .)

Although according to the 2015 CDC National Health Interview Survey (https://www.cdc.gov/nchs/nhis/shs/tables.htm), a probability sample survey conducted annually, an estimated 82% of 12-17 yr olds report excellent or very good health, 11% reported limitation in usual activities due to one or more chronic conditions, 10% missed 6-10 school days in the past year, 6% are uninsured, 6% have no usual place of healthcare, 10% have asthma, 12% have respiratory allergies, 10% have a learning disability, 14% have attention-deficit/hyperactivity disorder, and 18% take prescription medications routinely. In 2014 the mortality rate among adolescents 15-19 yr of age was 45 deaths per 100,000 population. While varying by gender, the leading **causes of death** overall among adolescents 15-19 yr of age are (1) unintentional injuries; (2) suicide; and (3) homicide (Table 136.2).

Table 136.2

Leading Causes of Death Among 15-19 Yr Olds by Gender, United States, 2014*

LEADING	MALE	FEMALE

CAUSES OF DEATH	Cause of Death	Mortality Rate per 100,000 Population	Cause of Death	Mortality Rate per 100,000 Population
#1	Accidents (unintentional injuries)	24.9	Accidents (unintentional injuries)	10.1
#2	Intentional self-harm (suicide)	13.0	Intentional self-harm (suicide)	4.2
#3	Assault (homicide)	11.2	Malignant neoplasms	2.5

[*] Based on data from Heron M: Deaths: leading causes for 2014, *Natl Vital Stat Rep* 65(5), 2016.

Within the adolescent population, **disparities in health** occur. Adolescent health outcomes and behaviors vary among populations that can be defined by race or ethnicity, gender, education or income, disability, geographic location (e.g., rural or urban), or sexual orientation. Health disparities result from multiple factors, including poverty, environmental threats, inadequate access to healthcare, individual and behavioral factors, and educational inequalities (Table 136.3).

Table 136.3

Access to Healthcare

Adolescents in the United States make fewer visits to physicians for ambulatory office visits than any other age group; school-age children and adolescents are more likely than younger children to have unmet health needs and delayed medical care. Adolescents who actually receive preventive care may still not have access to **time alone with their provider** to discuss confidential health issues such as STIs, HIV, or pregnancy prevention. Less than half (40%) of adolescents have time alone with their healthcare provider during a preventive healthcare visit; sexually experienced teens report sexual health discussions more often than nonsexually experienced teens, but the frequency is still low at 64% and 33.5% for sexually experienced females and males, respectively.

Young adults 18-24 yr are more likely to be insured with the 2010 Patient Protection and Affordable Care Act (**ACA**). Currently, the ACA permits children to receive benefits from their parents' health plans through age 26 yr. *Healthy People* provides science-based, 10-yr national objectives for measuring and improving the health of all Americans by establishing benchmarks and monitoring progress over time. The ***Healthy People 2020*** agenda includes 11 adolescent-specific objectives with a goal of improving the healthy development, health, safety, and well-being of adolescents and young adults over the next 10 yr (Table 136.4). This science-based initiative is centered around a framework for public health prevention priorities and actions to improve the health status of U.S. youth.

Table 136.4

Healthy People 2020 Adolescent Health (AH) Objectives

- **AH-1** : Increase the proportion of adolescents who have had a wellness checkup in the past 12 months
- **AH-2** : Increase the proportion of adolescents who participate in extracurricular and out-of-school activities
- **AH-3** : Increase the proportion of adolescents who are connected to a parent or other positive adult caregiver
    - **AH-3.1** : Increase the proportion of adolescents who have an adult in their lives with whom they can talk about serious problems

  - **AH-3.2** : Increase the proportion of parents who attend events and activities in which their adolescents participate
- **AH-4** : (Developmental) Increase the proportion of adolescents and young adults who transition to self-sufficiency from foster care
- **AH-5** : Increase educational achievement of adolescents and young adults
  - **AH-5.1** ***(Leading Health Indicator)*** : Increase the proportion of students who graduate with a regular diploma 4 years after starting 9th grade
  - **AH-5.2** : Increase the proportion of students who are served under the Individuals with Disabilities Education Act who graduate high school with a diploma
  - **AH-5.3** : Increase the proportion of students whose reading skills are at or above the proficient achievement level for their grade
  - **AH-5.4** : Increase the proportion of students whose mathematics skills are at or above the proficient achievement level for their grade
  - **AH-5.5** : Increase the proportion of adolescents who consider their school work to be meaningful and important
  - **AH-5.6** : Decrease school absenteeism among adolescents due to illness or injury
- **AH-6** : Increase the proportion of schools with a school breakfast program
- **AH-7** : Reduce the proportion of adolescents who have been offered, sold, or given an illegal drug on school property
- **AH-8** : Increase the proportion of adolescents whose parents consider them to be safe at school
- **AH-9** : (Developmental) Increase the proportion of middle and high schools that prohibit harassment based on a student's sexual orientation or gender identity
- **AH-10** : Decrease the proportion of public schools with a serious violent incident
- **AH-11** : Reduce adolescent and young adult perpetration of, as well as victimization by, crimes
  - **AH-11.1** : Decrease the rate of minor and young adult perpetration of violent crimes
  - **AH-11.2** : Decrease the rate of minor and young adult perpetration of serious property crimes

AH-11.3 : (Developmental) Decrease the percentage of counties and cities reporting youth gang activity

AH-11.4 : (Developmental) Reduce the rate of adolescent and young adult victimization from crimes of violence

CHAPTER 137

Delivery of Healthcare to Adolescents

Gale R. Burstein

Healthcare providers play an important role in nurturing healthy behaviors among adolescents, because the leading causes of death and disability among adolescents are preventable. Adolescence provides a unique opportunity to prevent or modify health conditions arising from behaviors that develop in the 2nd decade of life and that can lead to substantial morbidity and mortality, such as trauma, cardiovascular and pulmonary disease, type 2 diabetes, reproductive health disease, and cancer (see Chapter 132 , Table 132.4).

Health systems in each community should be in place to ensure comprehensive and high-quality care to adolescents. **Health insurance coverage** that is affordable, continuous, confidential, and not subject to exclusion for preexisting conditions should be available for all adolescents and young adults. **Comprehensive, coordinated benefits** should meet the developmental needs of adolescents, particularly for reproductive, mental health, dental, and substance abuse services. **Safety net providers and programs** that provide confidential services, such as school-based health centers, federally qualified health centers, family planning services, and clinics that treat sexually transmitted infections (**STIs**) in adolescents and young adults, need to have assured funding for viability and sustainability. **Quality-of-care** data should be collected and analyzed by age so that the performance measures for age-appropriate healthcare needs of adolescents are monitored. **Affordability** is important for access to preventive services. Family involvement should be encouraged, but **confidentiality** and adolescent consent are critically important. **Healthcare providers** , trained and experienced in adolescent care, should be available in all communities. Healthcare providers should be adequately compensated to support the range and intensity of services required to address the developmental and health service needs of adolescents. The development and dissemination of provider education about **adolescent preventive health guidelines** have been demonstrated to improve the content of recommended care (Table 137.1). The ease of recognition or expectation that an adolescent's needs can be addressed in a setting relates to the **visibility and flexibility** of sites and services. Staff at sites should be approachable, linguistically capable, and culturally competent. Health services should be coordinated to respond to goals for adolescent health at the local, state, and national levels. The coordination should address service financing and delivery in a manner that reduces disparities in care.

Table 137.1

Bright Futures/American Academy of Pediatrics Recommendations for Preventive Healthcare for 11-21 Yr Olds

	PERIODICITY AND INDICATIONS
HISTORY	Annual
MEASUREMENTS	
Body mass index	Annual
Blood pressure	Annual
SENSORY SCREENING	
Vision	At 12 yr and 15 yr visits or if risk assessment positive
Hearing	Screen with audiometry, including 6,000 and 8,000 Hz high frequencies once at 11-14 yr, once at 15-17 yr, and once at 18-21 yr.
DEVELOPMENTAL/BEHAVIORAL ASSESSMENT	
Developmental surveillance	Annual
Psychosocial/behavioral assessment	Annual
Depression screening	Annual for 12 yr and older
Tobacco, alcohol, and drug use assessment	If risk assessment positive
PHYSICAL EXAMINATION	Annual
PROCEDURES	
Immunization*	Annual
Hematocrit or hemoglobin	If risk assessment positive
Tuberculin test	If risk assessment positive
Dyslipidemia screening	Once at 9-11 yr, and once at 17-21 yr
STI screening	If sexually active
HIV screening †	Once between ages 15 and 18 yr Discuss and offer at earlier age and annually if risk assessment positive.
Cervical dysplasia screening ‡	Beginning at age 21 yr
ORAL HEALTH	Annual; refer to dental home
ANTICIPATORY	Annual §

GUIDANCE	

[*] Schedules per the Advisory Committee on Immunization Practices, published annually at http://www.cdc.gov/vaccines/schedules/hcp/index.html and http://redbook.solutions.aap.org/SS/Immunization_Schedules.aspx .

[†] CDC recommends universal, voluntary HIV screening of all sexually active people, beginning at age 13 yr. The American Academy of Pediatrics recommends offering routine HIV screening to all adolescents at least once by 16-18 yr of age and to those younger if at risk. US Preventive Services Task Force recommends offering routine HIV screening to all adolescents age 15 yr and older at least once and to those younger if at risk. Patients who test positive for HIV should receive prevention counseling and referral to care before leaving the testing site.

[‡] Screening for cervical cancer, April 2012, US Preventive Services Task Force. http://www.uspreventiveservicestaskforce.org/uspstf/uspscerv.htm .

[§] Refer to specific guidance by age as listed in *Bright Futures* guidelines.

HIV, Human immunodeficiency virus; STI, sexually transmitted infection.

Adapted from Hagan JF, Shaw JS, Duncan PM, editors: *Bright Futures: guidelines for health supervision of infants, children, and adolescents,* ed 4, Elk Grove Village, IL, 2017, American Academy of Pediatrics.

Although most adolescents in the United States have seen a healthcare provider in the past year and report a usual source of healthcare, adolescents are less likely to receive **preventive care** services. According to the 2011 National Health Interview Survey, an estimated 90% of 12-17 yr old U.S. adolescents had 1 or more contacts with a healthcare professional in the past year, 98% identify a usual source of care at a physician's office or clinic, and 17% made at least 1 emergency department visit in the past year. Uninsured adolescents are the least likely to receive care. In 2015, 63% of people under age 19 yr were covered at some point during the year by private insurance, and 43% of children had public health insurance at some point during 2015. However, even among adolescents who are fully insured with a usual source of care, most do not receive preventive healthcare. An analysis of claims data from a large Minnesota health plan with approximately 700,000 members found that among patients age 11-18 yr who were enrolled for at least 4 yr between 1998 and 2007, few received preventive care visits. One third of adolescents had no preventive care visits from age 13 through 17 yr, and another 40% had only a single such visit. Nonpreventive care visits were more frequent in all age-groups, averaging about 1 per yr at age 11 yr, climbing to about 1.5 per yr at age 17 yr. Among older adolescents, females had both more preventive care and more nonpreventive care visits than did males.

The **Patient Protection and Affordable Care Act (ACA)** , enacted in March 2010, has expanded access to both commercial health plans and Medicaid for young adults age 19-26 yr (Fig. 137.1). From June 2010 through June 2012, the proportion of young adults with insurance increased from 65.7% to 73.8%. Currently, ACA provisions require that commercial health plans (1) continue dependent coverage to 26 yr, regardless of the young adult's financial or dependent status, marriage, or educational enrollment; (2) mandate university and college student health plans to enhance consumer protections for students; (3) provide financial assistance for young adults to enroll into health insurance exchanges with incomes ranging from 133–399% of the federal poverty level in **Medicaid expansion states** ; and (4) offer preventive healthcare services free of any cost sharing, deductibles, or copayments. In states that have expanded Medicaid coverage, all adults with incomes <133% of the federal poverty level are eligible to enroll.

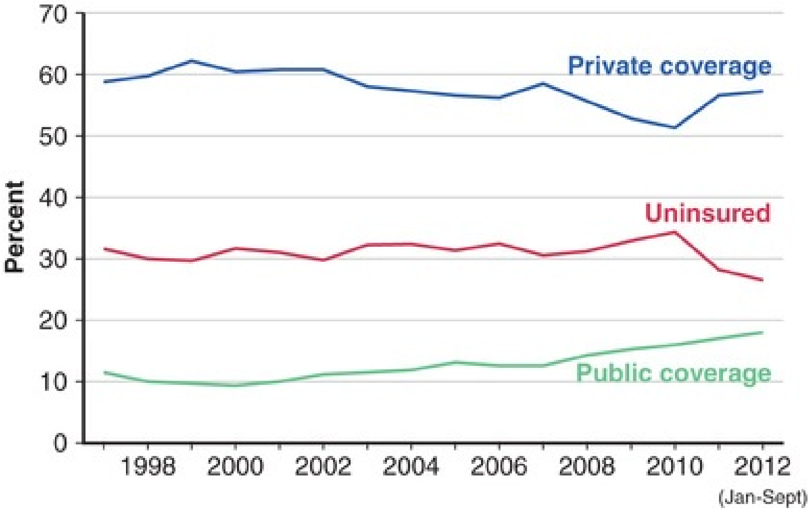

FIG. 137.1 Percentage of adults age 19-25 yr with health insurance by coverage type and percentage uninsured at the time of the interview: United States, 1997–September, 2012. *Note:* Estimates for 2012 are based on data collected in January through September. Data are based on household interviews of a sample of the civilian noninstitutionalized population. (Data from CDC/NCHS, National Health Interview Survey, 1997–2012, Family Core Component.)

The complexity and interaction of physical, cognitive, and psychosocial **developmental processes** during adolescence require sensitivity and skill on the part of the health professional (see Chapter 132). Health education and promotion, as well as disease prevention, should be the focus of every visit. In 2017 the American Academy of Pediatrics (AAP) in collaboration with the U.S.

Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, published the 4th edition of *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents* , which offers providers a strategy for delivery of adolescent preventive health services with screening and counseling recommendations for early, middle, and late adolescence (Table 137.2). *Bright Futures* is rooted in the philosophy of preventive care and reflects the concept of caring for children in a “medical home.” These guidelines emphasize effective partnerships with parents and the community to support the adolescent's health and development.

Table 137.2

Adolescent Screening Recommendations

	11-14 YR OLD VISIT	**15-17 YR OLD VISIT**	**18-21 YR OLD VISIT**
Universal Screening	**Action**	**Action**	**Action**
Cervical dysplasia*	N/A	N/A	Pap smear all young women at 21 yr visit
Depression	Adolescent depression screen beginning at 12 yr visit	Adolescent depression screen	Adolescent depression screen
Dyslipidemia	Lipid screen once at 9-11 yr	Lipid screen once at 17-21 yr	Lipid screen once at 17-21 yr
Hearing	Once at 11-14 yr Audiometry, including 6,000 and 8,000 Hz high frequencies	Once at 15-17 yr Audiometry, including 6,000 and 8,000 Hz high frequencies	Once at 18-21 yr Audiometry, including 6,000 and 8,000 Hz high frequencies
HIV †	Selective screening (see below)	HIV test once at 15-18 yr	HIV test once at 15-18 yr
Tobacco, alcohol, or drug use	Tobacco, alcohol, or drug use screen	Tobacco, alcohol, or drug use screen	Tobacco, alcohol, or drug use screen
Vision	At 12 yr visit Objective measure with age-appropriate visual-acuity measurement using HOTV or Lea symbols, Sloan letters, or Snellen letters	At 15 yr visit Objective measure with age-appropriate visual-acuity measurement using HOTV or Lea symbols, Sloan letters, or Snellen letters	N/A

		11-14 YR OLD VISIT	**15-17 YR OLD VISIT**	**18-21 YR OLD VISIT**
Selective	**Risk Assessment**	**Action If RA+**	**Action If RA+**	**Action If RA+**

Screening	**(RA)**			
Anemia	+ on risk screening questions	Hemoglobin or hematocrit	Hemoglobin or hematocrit	Hemoglobin or hematocrit
Dyslipidemia (if not universally screened at this visit	+ on risk screening questions and not previously screened with normal results	Lipid profile	Lipid profile	Lipid profile
HIV †	+ on risk screening questions	HIV test	HIV test (if not universally screened at this visit)	HIV test (if not universally screened at this visit)
Oral health (through 16 yr visit)	Primary water source fluoride deficient	Oral fluoridation supplementation	Oral fluoridation supplementation	N/A
STIs				
• Chlamydia • Gonorrhea	Sexually active females Sexually active males and + on risk screening questions	Chlamydia and gonorrhea NAAT (use tests appropriate for population and clinical setting)	Chlamydia and gonorrhea NAAT (use tests appropriate for population and clinical setting)	Chlamydia and gonorrhea NAAT (use tests appropriate for population and clinical setting)
• Syphilis	Sexually active and + on risk screening questions	Syphilis test	Syphilis test	Syphilis test
Tuberculosis	+ on risk screening questions	Tuberculin skin test	Tuberculin skin test	Tuberculin skin test
Vision at other ages	+ on risk screening questions at 11, 13, and 14 yr visits	Objective measure with age-appropriate visual-acuity measurement using HOTV or Lea symbols, Sloan letters, or Snellen letters	Objective measure with age-appropriate visual-acuity measurement using HOTV or Lea symbols, Sloan letters, or Snellen letters	Objective measure with age-appropriate visual-acuity measurement using HOTV or Lea symbols, Sloan letters, or Snellen letters

[*] Screening for Cervical Cancer. April 2012. U.S. Preventive Services Task Force. http://www.uspreventiveservicestaskforce.org/uspstf/uspscerv.htm .

[†] Centers for Disease Control and Prevention recommends universal, voluntary HIV screening of all sexually active people, beginning at age 13 yr. American Academy of Pediatrics recommends routine HIV screening offered to all adolescents at least once by 16-18 yr of age and to those younger if at risk. U.S. Preventive Services Task Force recommends routine HIV screening offered to all adolescents age 15 yr and older at least once and to those younger if at risk. Patients who test positive for HIV should receive prevention counseling and referral to care before leaving the testing site.

NA, Not applicable; NAAT, nucleic acid amplification test; STIs, sexually transmitted infections.

Adapted from Hagan JF, Shaw JS, Duncan PM, editors: *Bright Futures: guidelines for health supervision of infants, children, and adolescents,* ed 4, Elk Grove Village, IL, 2017, American

Academy of Pediatrics; and Bright Futures/American Academy of Pediatrics: Recommendations for Preventive Pediatric Health Care (Periodicity Schedule), 2017. https://www.aap.org/en-us/Documents/periodicity_schedule.pdf .

The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) currently recommends routine **adolescent vaccines** for universal administration beginning at the 11-12 yr old visit, or as soon as possible, (a) tetanus–diphtheria–acellular pertussis vaccine (Tdap), (b) the meningococcal conjugate vaccine (MCV4) with a booster at age 16 yr, and (c) the human papillomavirus vaccine (HPV) series (see Chapter 197). ACIP recommends annual influenza vaccination and hepatitis A virus (HAV) vaccination to adolescents and young adults who have not previously received the HAV vaccine series if immunity against HAV is desired or for those at increased risk for infection, such as men who have sex with men (MSM), injection drug users (IDU), and those with chronic liver disease or clotting factor disorders, or who live in areas that target older children for HAV vaccine.

The time spent on various elements of the screening will vary with the issues that surface during the assessment. For **gay and lesbian youth** (see Chapter 134), emotional and psychological issues related to their experiences, from fear of disclosure to the trauma of homophobia, may direct the clinician to spend more time assessing emotional and psychological supports in the young person's environment. For youth with **chronic illnesses or special needs** , the assessment of at-risk behaviors should not be omitted or deemphasized by assuming they do not experience the "normal" adolescent vulnerabilities.

137.1

Legal Issues

Gale R. Burstein

The rights of an individual, including those of adolescents, vary widely between nations. In the United States, the right of a minor to consent to treatment without parental knowledge differs between states and is governed by **state-specific**

minor consent laws . Some consent laws are based on a minor's status, such as minors who are emancipated, parents, married, pregnant, in the armed services, or mature. In some states, minors can be considered *emancipated* if they are or have served in the armed services or are living apart from parents and are economically independent through gainful employment. A *mature minor* is a minor who is emotionally and intellectually mature enough to give informed consent and who lives under the supervision of a parent or guardian. Courts have held that if a minor is mature, a physician is not liable for providing beneficial treatment. There is no formal process for recognition of a mature minor. The determination is made by the healthcare provider.

Some minor consent laws are based on services a minor is seeking, such as emergency care, sexual healthcare, substance abuse, or mental healthcare (Table 137.3). All 50 states and the District of Columbia explicitly allow minors to consent for their own health services for **STIs** . Approximately 25% of states require that minors be a certain age (generally 12-14 yr) before they can consent for their own care for STIs. No state requires parental consent for STI care or requires that providers notify parents that an adolescent minor child has received STI services, except in limited or unusual circumstances.

Table 137.3

Types of Minor Consent Statutes or Rules of Common Law That Allow for Medical Treatment of a Minor Patient Without Parental Consent

LEGAL EXCEPTIONS TO INFORMED CONSENT REQUIREMENT	MEDICAL CARE SETTING
The “emergency” exception	• The child is suffering from an emergent condition that places his or her life or health in danger. • The child's legal guardian is unavailable or unable to provide consent for treatment or transport. • Treatment or transport cannot be safely delayed until consent can be obtained. • The professional administers only treatment for emergent conditions that pose an immediate threat to the child.
The “emancipated minor” exception	• Married • Economically self-supporting and not living at home • Active-duty status in the military • In some states, a minor who is a parent or pregnant • Some states might require a court to declare the emancipation of a minor.
The “mature	Most states recognize a mature minor, in which a minor, usually ≥14 yr, displays sufficient

minor" exception	maturity and intelligence to understand and appreciate the benefits, risks, and alternatives of the proposed treatment and to make a voluntary and reasonable choice on the basis of that information. States vary or whether a judicial determination is required.
Exceptions based on specific medical condition (state laws vary)	Minor seeks: • Mental health services • Pregnancy and contraceptive services • Testing or treatment for HIV infection or AIDS • Sexually transmitted infection testing and treatment • Drug and alcohol addiction treatment

Data from American Academy of Pediatrics: Consent for emergency medical services for children and adolescents, *Pediatrics* 128:427–433, 2011.

Minors' right to consent for **contraceptive services** varies from state to state. Almost 50% of states and the District of Columbia explicitly authorize all minors to consent for their own contraceptive services; and 50% of states permit minors to consent for their own contraceptive services under specific circumstances, such as being married, a parent, currently or previously pregnant, over a certain age, or a high school graduate, or per physician's discretion.

A minor's right to consent for **mental healthcare** and **substance abuse** treatment services vary by state and age of minor, whether care is medical vs nonmedical (e.g., counseling), and whether care is delivered as an inpatient vs outpatient basis. Minor consent laws often contain provisions regarding confidentiality and disclosure, even when general state consent laws do not have such provisions.

The **confidentiality** of medical information and records of a minor who has consented for his or her own *reproductive healthcare* is governed by numerous federal and state laws. Laws in some states explicitly protect the confidentiality of STI or contraceptive services for which minors have given their own consent and do not allow disclosure of the information without the minor's consent. In other states, laws grant physicians discretion to disclose information to parents.

The confidentiality of medical information and records of a minor who has consented for his or her own healthcare is also governed by numerous federal and state laws. Laws in some states explicitly protect the confidentiality of STI, contraceptive, or mental health services for which minors have given their own consent, and do not allow disclosure of the information without the minor's consent. In other states, laws grant physicians discretion to disclose information to parents. Title X and Medicaid both provide confidentiality protection for family planning services provided to minors with funding from these programs.

Federal regulations issued under the Federal Health Insurance Portability and Accountability Act of 1996, known as the **HIPAA Privacy Rule** , defer to state and "other applicable laws" with respect to the question of whether parents have access to information about care for which a minor has given consent. Thus, both the state laws that either prohibit or permit disclosure of confidential information and the federal Title X and Medicaid laws that protect the confidentiality of care for adolescents are important under the HIPAA Privacy Rule in determining when confidential information about health services for minors can be disclosed to parents.

Billing for confidential services is complex. Commercial health plans send home an **explanation of benefit (EOB)** to the primary insured or the primary beneficiary, listing services rendered by the provider and reimbursed by the health plan. An EOB documenting that confidential health services were rendered to their adolescent dependent that is received by a parent may disclose those services. In addition, copayments automatically generated with certain billing codes for office visits and medications can be a barrier for adolescents receiving care, including treatment.

Providers may elect to establish a policy of discussing with their adolescent patients when medical records and other information will be disclosed and developing a mechanism to alert office staff as to what information in the chart is confidential. For legal and other reasons, a chaperone should be present whenever an adolescent female patient is examined by a male physician.

137.2

Screening Procedures

Gale R. Burstein

Interviewing the Adolescent

The preparation for a successful interview with an adolescent patient varies based on the history of the relationship with the patient. Patients (and their parents) who are going from preadolescence to adolescence while seeing the same provider should be guided through the transition. Although the rules for confidentiality are the same for new and continuing patients, the change in the **physician–patient relationship** , allowing more privacy during the visit and more autonomy in the health process, may be threatening for the parent as well as the adolescent. For new patients, the initial phases of the interview are more challenging given the need to establish rapport rapidly with the patient in order to meet the goals of the encounter. Issues of **confidentiality and privacy** should be explicitly stated along with the conditions under which that confidentiality may need to be altered, that is, in life- or safety-threatening situations. For new patients, the parents should be interviewed with the adolescent or before the adolescent to ensure that the adolescent does not perceive a breach of confidentiality. The clinician who takes time to listen, avoids judgmental statements and the use of street jargon, and shows respect for the adolescent's emerging maturity will have an easier time communicating with the adolescent. The use of open-ended questions, rather than closed-ended questions, will further facilitate history taking. (The closed-ended question, “Do you get along with your father?” leads to the answer “yes” or “no,” in contrast to the question, “What might you like to be different in your relationship with your mother?” which may lead to an answer such as, “I would like her to stop always worrying about me.”)

The **goals** of the interview or clinical encounter are to establish an information base, identify problems and issues from the patient's perspective, and identify problems and issues from the perspective of the clinician, based on knowledge of the health and other issues relevant to the adolescent age-group. The adolescent should be given an opportunity to express concerns and the reasons for seeking medical attention. The adolescent as well as the parent should be allowed to express the strengths and successes of the adolescent, in addition to communicating problems.

The effectiveness of an interview can be compromised when the interviewer is distracted by other events or individuals in the office, when extreme time limitations are obvious to either party, or when there is expressible discomfort with either the patient or the interviewer. The need for an **interpreter** when a patient is hearing impaired or if the patient and interviewer are not language compatible provides a challenge but not necessarily a barrier under most circumstances (see Chapter 11). Observations during the interview can be useful to the overall assessment of the patient's maturity, presence or absence of depression, and the parent–adolescent relationship. Given the key role of a successful interview in the screening process, adequate training and experience should be sought by clinicians providing comprehensive care to adolescent patients.

Psychosocial Assessment

A few questions should be asked to identify the adolescent who is having difficulty with **peer relationships** (Do you have a best friend with whom you can share even the most personal secret?), **self-image** (Is there anything you would like to change about yourself?), **depression** (What do you see yourself doing 5 yr from now?), **school** (How are your grades this year compared with last year?), **personal decisions** (Are you feeling pressured to engage in any behavior for which you do not feel you are ready?), and an **eating disorder** (Do you ever feel that food controls you, rather than vice versa?). *Bright Futures* materials provide questions and patient encounter forms to structure the assessments. The **HEADS/SF/FIRST** mnemonic, basic or expanded, can be useful in guiding the interview if encounter forms are not available (Table 137.4). Based on the assessments, appropriate counseling or referrals are recommended for more thorough probing or for in-depth interviewing.

Table 137.4

Adolescent Psychosocial Assessment: HEADS/SF/FIRST Mnemonic

***H* ome.** Space, privacy, frequent geographic moves, neighborhood

***E* ducation/School.** Frequent school changes, repetition of a grade/in each subject, teachers' reports, vocational goals, after-school educational clubs (e.g., language, speech, math), learning disabilities

***A* buse.** Physical, sexual, emotional, verbal abuse; parental discipline

***D* rugs.** Tobacco, electronic cigarettes or vaping devices, alcohol, marijuana, inhalants, “club drugs,” “rave” parties, others; drug of choice, age at initiation, frequency, mode of intake, rituals, alone or with peers, quit methods, number of attempts

***S* afety.** Seat belts, helmets, sports safety measures, hazardous activities, driving while intoxicated

***S* exuality/*S* exual Identity.** Reproductive health (use of contraceptives, presence of sexually transmitted infections, feelings, pregnancy)

***F* amily and *F* riends**

Family: Family constellation; genogram; single/married/separated/divorced/blended family; family occupations and shifts; history of addiction in first- and second-degree relatives; parental attitude toward alcohol and drugs; parental rules; chronically ill, physically or mentally challenged parent

Friends: Peer cliques and configuration (“preppies,” “jocks,” "nerds," "computer geeks," cheerleaders), gang or cult affiliation

***I* mage.** Height and weight perceptions, body musculature and physique, appearance (including dress, jewelry, tattoos, body piercing as fashion trends or other statement)

***R* ecreation.** Sleep, exercise, organized or unstructured sports, recreational activities (television, video games, computer games, internet and chat rooms, church or community youth group activities [e.g., Boy (BSA)/Girl Scouts; Big Brother/Sister groups, campus groups]). How many hours per day, days per week involved?

***S* pirituality and Connectedness.** Use HOPE* or FICA [†] acronym; adherence, rituals, occult practices, community service or involvement

***T* hreats and Violence.** Self-harm or harm to others, running away, cruelty to animals, guns, fights, arrests, stealing, fire setting, fights in school

Physical Examination

Vision Testing

The pubertal growth spurt may involve the optic globe, resulting in its elongation and myopia in genetically predisposed individuals (see Chapter 636). Vision testing should therefore be performed to detect this problem before it affects school performance.

Audiometry

Highly amplified music of the kind enjoyed by many adolescents may result in hearing loss or tinnitus (see Chapter 654). A hearing screening is recommended by the *Bright Futures* guidelines for adolescents who are exposed to loud noises regularly, have had recurring ear infections, or report problems.

Blood Pressure Determination

Criteria for a diagnosis of hypertension are based on age-specific norms that increase with pubertal maturation (see Chapter 449). An individual whose blood pressure (BP) exceeds the 95th percentile for his or her age is suspect for having hypertension, regardless of the absolute reading. Those adolescents with BP between the 90th and 95th percentiles should receive appropriate counseling relative to weight and have a follow-up examination in 6 mo. Those with BP above the 90th percentile should have their BP measured on 3 separate occasions to determine the stability of the elevation before moving forward with an intervention strategy. The technique is important; false-positive results may be obtained if the cuff covers less than two thirds of the upper arm. The patient should be seated, and an average should be taken of the 2nd and 3rd consecutive readings, using the change rather than the disappearance as the diastolic pressure. Most adolescents with BP elevation have labile hypertension. If BP is below 2 standard deviations (SD) for age, anorexia nervosa and Addison disease should be considered.

Scoliosis

See Chapter 699 .

Approximately 5% of male and 10–14% of female adolescents have a mild curvature of the spine. This is 2-4 times the rate in younger children. Scoliosis is typically manifested during the peak of the height velocity curve, at approximately 12 yr in females and 14 yr in males. Curves measuring >10 degrees should be monitored by an orthopedist until growth is complete.

Breast Examination

See Chapters 141 and 556 .

Visual inspection of the young and middle adolescent female adolescent's breasts is performed to evaluate progression of sexual maturation and provide reassurance about development.

Scrotum Examination

Visual inspection of the young and middle adolescent male testicles is performed to evaluate progression of sexual maturation and provide reassurance about development. The peak incidence of germ cell tumors of the testes is in late adolescence and early adulthood. Palpation of the testes may have an immediate yield and should serve as a model for instruction of self-examination. Because varicoceles often appear during puberty, the examination also provides an opportunity to explain and reassure the patient about this entity (see Chapter 560).

Pelvic Examination

See Chapter 563 .

Laboratory Testing

The increased incidence of iron-deficiency **anemia** after menarche directs the performance of a hematocrit annually in females with moderate to heavy menses. The reference standard for this test changes with progression of puberty, as estrogen suppresses erythropoietin (see Chapter 474). Populations with nutritional risk should also have the hematocrit monitored. Androgens have the opposite effect, causing the hematocrit to rise during male puberty; sexual maturity rating (SMR) 1 males have an average hematocrit of 39%, whereas those who have completed puberty (SMR 5; see Chapter 132) have an average value of 43%. **Tuberculosis (TB)** testing is important in adolescents with risk factors, such as an adolescent with HIV, living in the household with someone with HIV, the incarcerated or homeless adolescent, adolescents from a country where TB is common, or those with other risk factors, because puberty has been shown to activate this disease in those not previously treated. **Hepatitis C virus (HCV)** screening should be offered to adolescents who report risk factors, such as IDU, received blood products or organ donation before 1992, or long-term hemodialysis. Almost 10% of all HCV cases reported to CDC in 2015 were among 15-24 yr olds. CDC HCV surveillance data demonstrates that from 2006 to 2014, the number of reported HCV infections among females of reproductive age (15-44 yrs) doubled. Nearly half of those cases were among females 15-30 yrs of age. Two thirds (67%) of those with a known risk factor reported intravenous drug use.

Sexually active adolescents should undergo screening for **STIs** per CDC guidelines, regardless of symptoms (see Chapter 146). There are clear indications for chlamydia and gonorrhea screening of females ≤24 yr old, but less sufficient evidence to support routine screening in young men. Based on feasibility, efficacy, and cost-effectiveness, evidence is insufficient to recommend routine chlamydia screening in all sexually active young men. However, screening of sexually active young males should be considered in clinical settings associated with high prevalence of chlamydia (e.g., adolescent clinics, correctional facilities, sexually transmitted disease clinics) and should be offered to all young MSM. **HIV** screening should be discussed and offered at least once to all adolescents aged 15-18 yr and to younger and older adolescents who are at increased risk. Routine screening of adolescents who are asymptomatic for certain STIs (e.g., syphilis, trichomoniasis, herpes simplex virus, HPV) is not recommended. However, young MSM and pregnant adolescent females might require more thorough evaluation for all sexually transmitted diseases. Because cervical cancer incidence is low and complications from procedures may outweigh benefits of screening adolescent females, cervical cancer screening should not begin until age 21 yr.

CHAPTER 138

Transitioning to Adult Care

Cynthia M. Holland-Hall, Gale R. Burstein, Lisa K. Tuchman

The importance of successfully transitioning the care of adolescents with **special healthcare needs (SHCN)** from pediatric to adult services has been recognized for more than 2 decades. Successful transition is associated with improved health outcomes and quality of life; poorly managed transition may lead to loss of a medical home and worsening of chronic disease control and previous care.

The American Academy of Pediatrics, in conjunction with other key professional societies, published detailed, comprehensive guidelines for incorporating transition services into the **medical home** for all adolescents, regardless of the presence or absence of SHCN. These guidelines are based on expert opinion because the evidence on transition outcomes is limited. This clinical report emphasizes that **transition** encompasses much more than simply the transfer of care to another provider. The guidelines go beyond recommendations for the pediatric medical home by providing guidance and practice-based resources for implementing elements of transition support in family medicine and internal medicine practices. This includes providing assistance for the patient in adapting to an adult model of healthcare delivery. Table 138.1 represents the key elements of healthcare transition. Tools to assist providers with these steps are available online from the National Center for Health Care Transition Improvement (www.gottransition.org).

Table 138.1

Key Elements of the Transition of Healthcare Process

- **Written transition policy** to be shared with youth, families, providers, and staff, explaining the process and the responsibilities of all team members

- **Transitioning youth registry** to track the progress of each patient through the transition process
- **Longitudinal readiness checklists** assessing the youth's ability for independence, self-management, and communicating with the adult healthcare system, as well as the family's readiness to assist the patient in achieving these goals
- **Written transition plan** documenting the steps to be conducted to meet the needs identified in the readiness assessment, as well as identifying appropriate adult care resources
- For youth with SHCN, expanded transition services, including attention to insurance, entitlements, guardianship, and vocational needs, in addition to adult subspecialty care
- Appropriate communication between the pediatric and adult medical home and subspecialists, including a **portable medical summary** and care plan delivered to the patient and caregivers
- Transfer of care, within the 18-21 yr old range, to adult providers, to whom pediatric providers continue to serve as a resource until transition is complete

The process begins with the development of a transition policy and its dissemination to all families of young adolescents, ensuring that families understand that transition planning will be an element of health maintenance and chronic care management visits throughout the adolescent years. By middle adolescence, a transition plan should be developed with the youth and family caregivers and updated at subsequent visits until the patient is ready for implementation of the adult care model in early adulthood. Periodic **readiness assessments** are key to plan and anticipate challenges. Critical to the transition process is **skills training** for the adolescent in communication, self-advocacy, and self-care. Some youth with SHCN depend on caregivers for navigating the healthcare system on their behalf, and it is not realistic to expect increased independence. For these youth, addressing guardianship, long-term care planning, and advanced directives are important. **Care coordination** has been found to facilitate navigation and engagement in an adult-oriented health system, especially for adolescents with SHCN. The goal is to help all youth maximize their potential as they become young adults.

CHAPTER 139

Violent Behavior

Michael N. Levas, Marlene D. Melzer-Lange

Violence is recognized by the World Health Organization (WHO) as a leading worldwide public health problem. WHO defines **violence** as “the intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community that either results in or has a high likelihood of resulting in injury, death, psychologic harm, maldevelopment or deprivation” (see Chapter 14). Youths may be perpetrators, victims, or observers of violence (or any combination of the 3 roles), with varying severity of impact on the individual, family, and larger community. Risk factors for youth violence include poverty, relative social disadvantage, war, substance abuse, mental health disorders, and poor family functioning.

Epidemiology

In 2015, **homicide** in the United States was the 3rd leading cause of death for 10-24 yr olds, totaling 4,979 deaths, which were largely males (87%) killed by a handgun (90.1%). The 2015 homicide rate for teens ages 12-17 yr was 3.1/100,000 youth, down 65% from 8.4/100,000 youth in 1993. WHO reports that other than the United States, where the youth and young adult homicide rate was 11 per 100,000, most countries with homicide rates above 10 per 100,000 are developing nations or countries with rapid socioeconomic changes. In the United States the prevalence of behaviors that contribute to violence has not decreased since 1999; fighting, weapon carrying, and gang involvement remain prevalent among youth. Gang-related homicides among youth in 5 major U.S. cities are more likely to involve young (15-19 yr) males (80%), racial/ethnic minorities (73%), and a firearm (90%) in comparison to homicides unrelated to gang activity. In addition, gang homicides are more likely to occur in public places, in the afternoon/evening hours, and rarely are related to drug trade/use. Furthermore, the rate of homicide in youth had been declining but showed an increase in 2015 (Fig. 139.1).

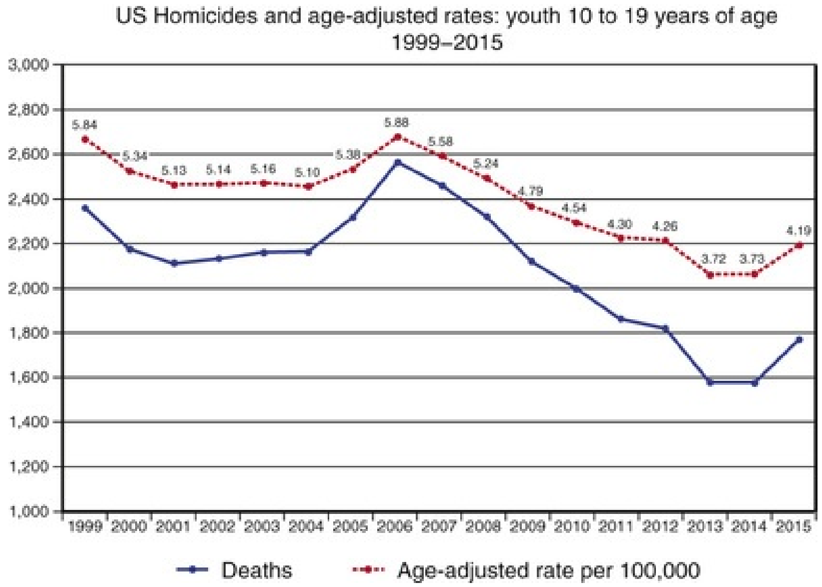

FIG. 139.1 Homicides and age-adjusted rates: youth age 10-19 yr, United States, 1999–2015. (Data from Centers for Disease Control and Prevention, National Center for Injury Prevention and Control, Web-based Injury Statistics Query and Reporting System [WISQARS], 1999–2015. http://www.cdc.gov/ncipc/wisqars .)

Adolescent reports of **physical fighting** have decreased from 42% in 1991 to 23% in 2015. Violence at U.S. schools remains a significant problem, however, with 7.8% of students reporting being in a physical fight on school property 1 or more times in the preceding 12 mo. The 2015 Youth Risk Behavior Surveillance System reported 16.2% of youths overall carried a weapon such as a gun, knife, or club in the last 30 days; 4.1% carried the weapon to school; and 6.0% reported being threatened or injured with a type of weapon on school property. Males are more likely than females to carry a gun or weapon and therefore may need more support and engagement at home and at school. **Weapon carrying** is highest among white males overall, which may begin as early as 9th grade. These violence-related behaviors at school affect the general students' perception of safety. More than 5.6% of students did not go to school on 1 or more days in the preceding 30 days because they felt it was unsafe. School-based prevention programs initiated at the elementary school level have been found to decrease violent behaviors in students. Increased surveillance of students is warranted both on and around school property to improve student safety.

Dating violence (or intimate partner violence) occurs between 2 people in a close relationship and can be physical (punching, kicking, hitting, shoving), emotional (shaming, bullying, controlling, stalking), or sexual (forcing partner to engage in a sexual act when he/she does not consent to it). Incidents of dating violence often occur during the adolescent years, with 22.4% of women and 15% of men experiencing some type of partner violence between the ages of 11 and 17 yr. The highest prevalence rates are seen in black students and older students. It may start with teasing, name calling, or shaming but often progresses electronically, as frequent calls, texting, or posting sexual pictures of a partner on social media. Risk factors for being a victim of dating violence includes those who use alcohol, believe dating violence is acceptable, have lack of parental supervision, or have a friend who is in a violent relationship. Most teens do not report the behaviors due to fear of retaliation from the partner. Teens who are victims of dating violence are more likely to experience decreased school performance, have thoughts about suicide, use drugs and alcohol, develop an eating disorder, experience depression, and are more likely to be victimized during college. School-based prevention programs that address attitudes and behaviors linked with dating violence, such as **Safe Dates** and **Dating Matters** , offer training experiences to change social norms among teens.

Etiology

WHO places youth violence in a model within the context of 3 larger types of violence: self-inflicted, interpersonal, and collective. **Interpersonal violence** is subdivided into violence largely between family members or partners and includes child abuse. **Community violence** occurs between individuals who are unrelated. **Collective violence** incorporates violence by people who are members of an identified group against another group of individuals with social, political, or economic motivation. The types of violence in this model have behavioral links, such that child abuse victims are more likely to experience violent and aggressive interpersonal behavior as adolescents and adults. Overlapping risk factors for the types of violence include firearm availability, alcohol use, and socioeconomic inequalities. The benefit to identifying common risk factors for the types of violence lies in the potential for intervening with prevention efforts and gaining positive outcomes for more than 1 type of violent behavior. The model further acknowledges 4 categories that explore the potential nature of violence as involving physical, sexual, or psychological force, and deprivation.

The social-ecologic model of public health focuses on both population-level and individual-level determinants of health and their respective interventions. On the individual level, there may be 2 types of antisocial youth: life course persistent and limited. **Life course–limited offenders** have no childhood aberrant behaviors and are more likely to commit *status* offenses such as vandalism, running away, and other behaviors symbolic of their struggle for autonomy from parents. **Life course–persistent offenders** exhibit aberrant behavior in childhood, such as problems with temperament, behavioral development, and cognition; as adolescents they participate in more *victim-oriented* crimes. The existence of **adverse childhood events** foretells future health issues and subsequent violence. This hypothesis proposes that precursors such as child abuse and neglect, a child witnessing violence, adolescent sexual and physical abuse, and adolescent exposure to violence and violent assaults predispose youths to outcomes of violent behavior, violent crime, delinquency, violent assaults, suicide, or premature death. This public health model also emphasizes the community environment and other external influences. An additional common paradigm for high-risk violence behavior poses a balance of risk and protective factors at the individual, family, and community levels.

Clinical Manifestations

The identified risk factors for youth violence include poverty, association with delinquent peers, poor school performance or low education status, disconnection from adult role models or mentors, prior history of violence or victimization, poor family functioning, childhood abuse, substance abuse, and certain mental health disorders. The most common disorders associated with **aggressive behavior** in adolescents are mental retardation, learning disabilities, moderately severe language disorders, and mental disorders such as attention-deficit/hyperactivity disorder (ADHD) and mood disturbances. The link between severe mental illness and violent behaviors is strongest for those with coexisting alcohol or substance abuse or dependence.

Inability to master prosocial skills such as the establishment and maintenance of positive family/peer relations and poor resolution of conflict may put adolescents with these disorders at higher risk of physical violence and other risky behaviors. **Conduct disorder** and **oppositional defiant disorder** are specific psychiatric diagnoses whose definitions are associated with violent behavior (Table 139.1). They occur with other disorders such as ADHD (see Chapter 49) and increase an adolescent's vulnerability for juvenile delinquency, substance use or abuse, sexual promiscuity, adult criminal behavior, incarceration, and antisocial personality disorder. Other co-occurring risk factors for youth violence include use of anabolic steroids, gang tattoos, belief in one's premature death, preteen alcohol use, and placement in a juvenile detention center.

Table 139.1

Oppositional Defiant Disorder, Conduct Disorder, and Juvenile Delinquency

PSYCHIATRIC DISORDER LABELS		**Legal Label Juvenile Delinquency**
Oppositional Defiant Disorder	**Conduct Disorder**	
Recurrent pattern of negativistic, defiant, disobedient, and hostile behavior toward authority figures that has a significant adverse effect on functioning (e.g., social, academic, occupational)	Repetitive and persistent pattern of behavior that violates the basic rights of others or major age-appropriate societal norms or rules	Offenses that are illegal because of age; illegal acts
Examples: losing temper; arguing with adults; defying or refusing to comply with request or rules of adults; annoying behavior; blaming others; being irritable, spiteful, resentful	Examples: physical fighting, deceitfulness, stealing, destruction of property, threatening or causing physical harm to people or animals, driving without a license, prostitution, rape (even if not adjudicated in the legal system)	Examples: single or multiple instances of being arrested or adjudicated for any of the following: stealing, destruction of property, threatening or causing physical harm to people or animals, driving without a license, prostitution, rape
Diagnosed by a mental health clinician	Diagnosed by a mental health practitioner	Adjudicated in the legal system

From Greydanus DE, Pratt HD, Patel DR, et al: The rebellious adolescent, *Pediatr Clin North Am* 44:1460, 1997.

Diagnosis

The assessment of an adolescent at risk or with a history of violent behavior or victimization should be a part of the health maintenance visit of all adolescents. The answers to questions about recent history of involvement in a physical fight, carrying a weapon, or firearms in the household, as well as concerns that the adolescent may have about personal safety, may suggest a problem requiring a more in-depth evaluation. The **FISTS** mnemonic provides guidance for structuring the assessment (Table 139.2). The additional factors of physical or sexual abuse, serious problems at school, poor school performance and attendance, multiple incidents of trauma, substance use, and symptoms associated with mental disorders are indications for evaluation by a mental health professional. In a situation of acute trauma, assault victims are not always forthcoming about the circumstances of their injuries for fear of retaliation or police involvement. Stabilization of the injury or the gathering of forensic evidence in sexual assault is the treatment priority; however, once this is achieved, addressing a more comprehensive set of issues surrounding the assault is appropriate.

Table 139.2

FISTS Mnemonic to Assess an Adolescent's Risk of Violence

F: Fighting (How many fights were you in last year? What was the last?)
I: Injuries (Have you ever been injured? Have you ever injured someone else?)
S: Sex (Has your partner hit you? Have you hit your partner? Have you ever been forced to have sex?)
T: Threats (Has someone with a weapon threatened you? What happened? Has anything changed to make you feel safer?)
S: Self-defense (What do you do if someone tries to pick a fight? Have you carried a weapon in self-defense?)

The FISTS mnemonic is adapted with permission from the Association of American Medical Colleges. Alpert EJ, Sege RD, Bradshaw YS: Interpersonal violence and the education of physicians, *Acad Med* 72:S41–S50, 1997.

Treatment

In the patient with acute injury secondary to violent assault, the treatment plan should follow standards established by the American Academy of Pediatrics model protocol, which includes the stabilization of the injury, evaluation and treatment of the injury, evaluation of the assault circumstance, psychological evaluation and support, social service evaluation of the circumstance surrounding the assault, and a treatment plan on discharge that is designed to protect the adolescent from subsequent injury episodes, prevent retaliation, and minimize the development of psychological disability. Victims as well as witnesses of violence are at risk for posttraumatic stress disorder and future aggressive or violent behavior. Utilizing a **trauma-informed care** approach enables providers to help these victims and witnesses so that they can develop linkages to recovery and resilience. **Hospital-based violence intervention programs** have shown success by supporting youth who have sustained a violent injury in the emergency department, hospital, or community.

Multiple treatment modalities are used simultaneously in managing adolescents with persistent violent and aggressive behavior and range from cognitive-behavioral therapy involving the individual and family to specific family interventions (parent management training, multisystemic treatment) and pharmacotherapy. Treatment of comorbid conditions, such as ADHD, depression, anxiety, and substance abuse, appears to reduce aggressive behavior.

Prevention

The WHO recognizes a multifactorial approach to prevention: parenting and early childhood development strategies; school-based academic and social skills development strategies, strategies for young people at higher risk of or already involved in violence, and community-and society-level strategies (Table 139.3). **Parenting and early childhood development approaches** concentrate on working with families to provide nonviolent parenting through home visitation and parent groups as well as teaching coping strategies and nonviolent conflict resolution for all children and families. **School-based social skills development strategies** focus on students' families and peer relationships, especially those with the potential to trigger aggressive or violent responses. Solutions include improving skills in coping or problem solving in bullying, peer mediation, dating violence prevention, and after-school programs. **Strategies for young people at higher risk of, or already involved in, violence** include therapeutic mental health approaches, crime victim services, vocational training, mentoring, and gang intervention. These youth are at highest risk for repeat injury or incarceration. **Community- and societal-level approaches** include broader advocacy and legislative actions, as well as changing the cultural norm toward violent behaviors.

Table 139.3

WHO Youth Violence Prevention Strategies: Effectiveness by Context

STRATEGIES	CONTEXT/PROGRAMS	EFFECTIVENESS
Parenting and early childhood development strategies	Home visiting programs	?
	Parenting programs	+
	Early childhood development programs	+
School-based academic and social skills development strategies	Life and social skills development	+
	Bullying prevention	+
	Academic enrichment programs	
	Dating violence prevention programs	+
	Financial incentives for adolescents to attend school	?
	Peer mediation	+/−
	After-school and other structured leisure-time activities	?
Strategies for young people at higher risk of, or already involved in, violence	Therapeutic approaches	+
	Vocational training	?
	Mentoring	?
	Gang and street violence prevention programs	?
Community- and society-level strategies	“Hot spots” policing	+
	Community- and problem-oriented policing	+
	Reducing access to and the harmful use of alcohol	+
	Drug control programs	+
	Reducing access to and misuse of firearms	+
	Spatial modification and urban upgrading	+
	Poverty deconcentration	+

+, Promising (strategies that include 1 or more programs supported by at least 1 well-designed study showing prevention of perpetration and/or experiencing of youth violence, or at least 2 studies showing positive changes in key risk or protective factors for youth violence).

?, Unclear because of insufficient evidence (strategies that include 1 or more programs of unclear effectiveness).

+/−, Unclear because of mixed results (strategies for which the evidence is mixed; some programs have a significant positive effect and others a significant negative effect on youth violence).

From World Health Organization (WHO) Library Cataloguing-in Publication Data, Preventing youth violence: an overview of the evidence, 2015.

A specific prevention strategy can incorporate several approaches, such as the handgun/firearm prevention recommendations that include gun-lock safety, public education, and legislative advocacy. Other efforts are directed toward establishing a national database to track and define the problem of youth violence. The **National Violent Death Reporting System** collects and analyzes violent death data from 40 states and aims to improve surveillance of current trends, to share information state to state, to build partnerships among state and community organizations, and to develop and implement prevention and intervention programs. The Centers for Disease Control and Prevention characterizes specific successful prevention programs and summarizes program content on its website (www.cdc.gov).

CHAPTER 140

Substance Abuse

Cora Collette Breuner

Although varying in percentages by nation and culture, a substantial proportion of adolescents will engage in the use of a wide range of substances, including alcohol, tobacco, natural and synthetic marijuana, opiates, and stimulants. Their reactions to and the consequences of these exposures are influenced by a complex interaction among biologic and psychosocial development, environmental messages, legality, and societal attitudes. The potential for adverse outcomes even with occasional use in adolescents, such as motor vehicle crashes and other injuries, is sufficient justification to consider any drug use in adolescents a considerable risk.

Individuals who initiate drug use at an early age are at a greater risk for becoming addicted than those who try drugs in early adulthood. Drug use in younger adolescents can act as a substitute for developing age-appropriate coping strategies and enhance vulnerability to poor decision-making. First use of the most commonly used drug (alcohol) occurs before age 18 yr, with 88% of people reporting age of first alcohol use at <21 yr old, the legal drinking age in the United States. Interestingly, inhalants have been identified as a popular first drug for youth in 8th grade (age 13-14 yr).

When drug use begins to negatively alter functioning in adolescents at school and at home, and risk-taking behavior is seen, intervention is warranted. Serious drug use is a pervasive phenomenon and infiltrates every socioeconomic and cultural segment of the population. It is one of the costliest and most challenging public health problems facing all societies and cultures. The challenge to the clinician is to identify youths at risk for substance abuse and offer early intervention. The challenge to the community and society is to create norms that decrease the likelihood of adverse health outcomes for adolescents and promote and facilitate opportunities for adolescents to choose healthier and safer options.

Recognizing those drugs with the greatest *harm* , and at times focusing on *harm reduction* with or without abstinence, is an important modern approach to adolescent substance abuse (Figs. 140.1 and 140.2).

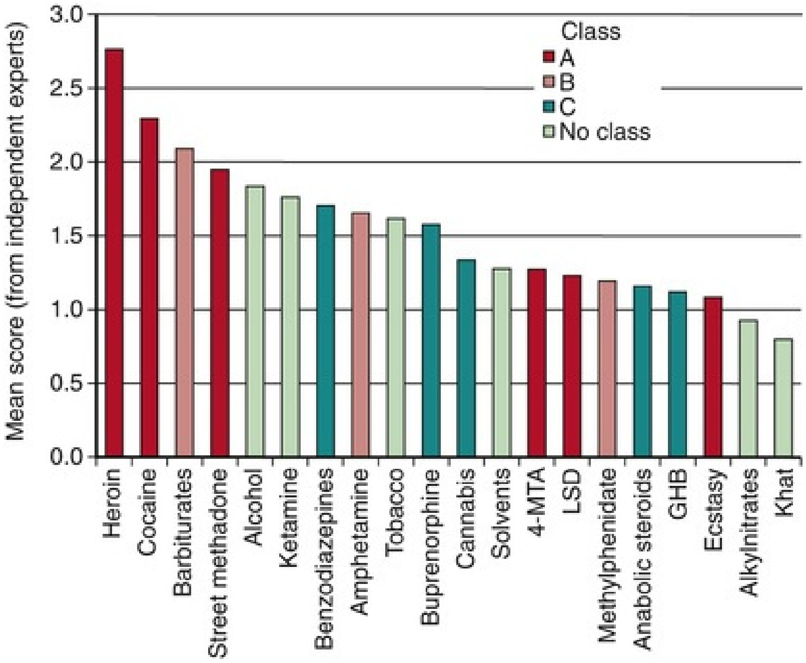

FIG. 140.1 Mean harm scores for 20 substances as determined by an expert panel based on 3 criteria: physical harm to user; potential for dependence; and effect on family, community, and society. Classification under the Misuse of Drugs Act, when appropriate, is shown by the color of each bar. Class A drugs are deemed potentially most dangerous; class C least dangerous. (From Nutt D, King LA, Saulsbury W, et al: Development of a rational scale to access the harm of drugs of potential misuse, *Lancet* 369:1047–1053, 2007.)

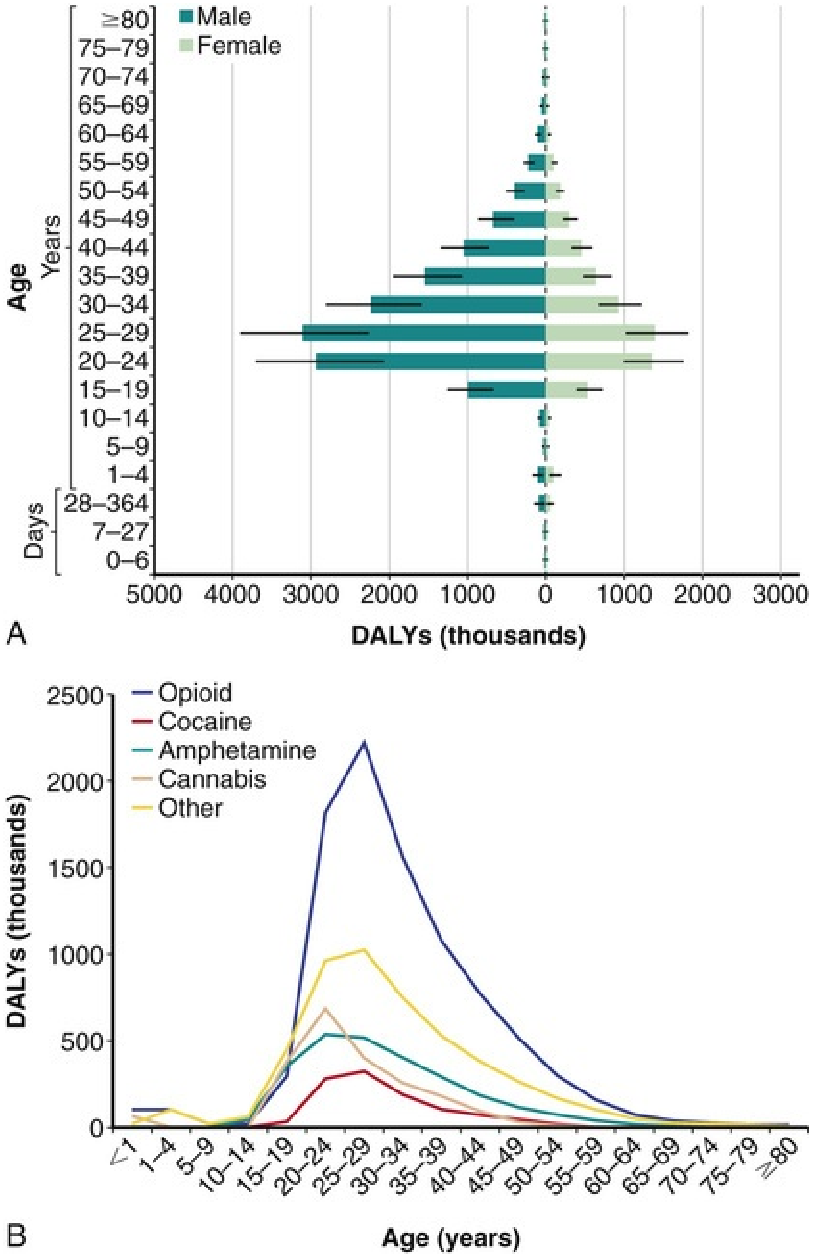

FIG. 140.2 Total burden (DALYs) of drug dependence by age and sex in 2010. A, DALYs attributable to drug dependence, by age and sex. B, DALYs attributable to each type of drug dependence by age. DALYs, Disability-adjusted life years. (From: Degenhardt L, Whitford HA, Ferrari AJ, et al: Global burden of disease attributable to illicit drug use and dependence: findings from the Global Burden of Disease study 2010, *Lancet* 382:1569, 2013.)

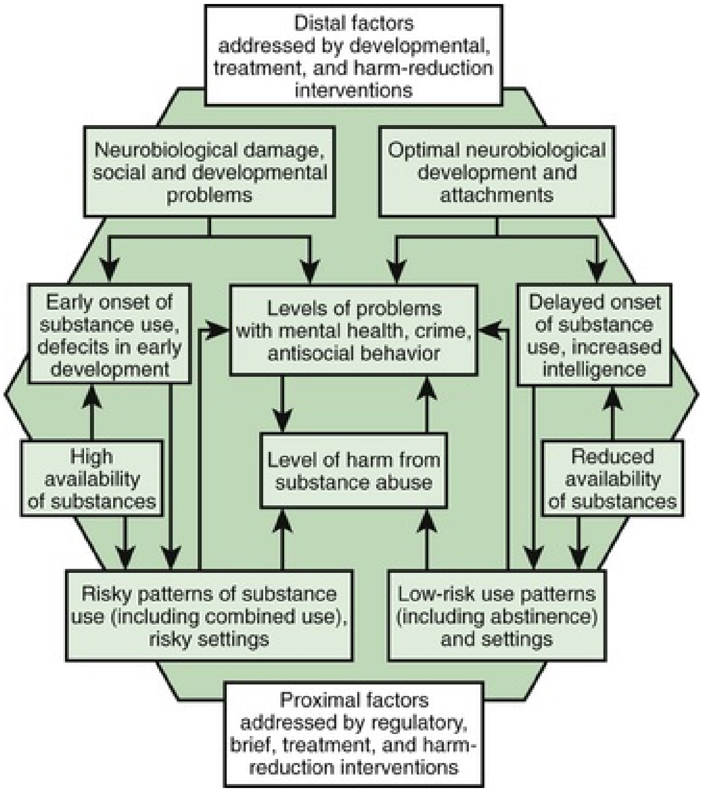
Etiology

Substance abuse has multifactorial origins (Fig. 140.3). Biologic factors, including genetic predisposition, are established contributors. Behaviors such as rebelliousness, poor school performance, delinquency, and criminal activity and personality traits such as low self-esteem, anxiety, and lack of self-control are frequently associated with or predate the onset of drug use. Psychiatric disorders often coexist with adolescent substance use. Conduct disorders and antisocial personality disorders are the most common diagnoses coexisting with substance abuse, particularly in males. Teens with depression (see Chapter 39.1), attention deficit disorder (Chapter 49), anxiety (Chapter 38), and eating disorders (Chapter 41) have high rates of substance use. The determinants of adolescent substance use and abuse are explained using numerous theoretical models, with factors at the individual level, the level of significant relationships with others, and the level of the setting or environment. Models include a balance of risk and protective or coping factors contributing to individual differences among adolescents with similar risk factors who escape adverse outcomes.



Distal factors addressed by developmental, treatment, and harm-reduction interventions
Neurobiological damage, social and developmental problems
Optimal neurobiological development and attachments
Early onset of substance use, defects in early development
Levels of problems with mental health, crime, antisocial behavior
Delayed onset of substance use, increased intelligence
High availability of substances
Level of harm from substance abuse
Reduced availability of substances
Risky patterns of substance use (including combined use), risky settings
Low-risk use patterns (including abstinence) and settings
Proximal factors addressed by regulatory, brief, treatment, and harm-reduction interventions

FIG. 140.3 Protection and risk model for distal and proximal determinants of risky substance use and related harms. (From Toumbourou JW, Stockwell T, Neighbors C, et al: Interventions to reduce harm associated with adolescent substance use, *Lancet* 369:1391–1401, 2007.)

Risk factors for adolescent *drug use* may differ from those associated with adolescent *drug abuse* . Adolescent *use* is more commonly related to social and peer factors, whereas *abuse* is more often a function of psychological and biologic factors. The likelihood that an otherwise normal adolescent would experiment with drugs may depend on the availability of the drug to the adolescent, the perceived positive or otherwise functional value to the adolescent, the perceived risk associated with use, and the presence or absence of restraints, as determined by the adolescent's cultural or other important value systems. An adolescent who abuses drugs may have genetic or biologic factors coexisting with dependence on a particular drug for coping with day-to-day activities.

Specific historical questions can assist in determining the severity of the drug problem through a rating system (Table 140.1). The type of drug used (marijuana vs heroin), the circumstances of use (alone or in a group setting), the frequency and timing of use (daily before school vs occasionally on a weekend), current mental health status, and general functional status, including sleep habits and screen use, should all be considered in evaluating any child or adolescent found to be using a drug. The stage of drug use/abuse should also be considered (Table 140.2). A teen may spend months or years in the experimentation phase trying a variety of illicit substances, including the most common drugs: cigarettes, alcohol, and marijuana. Often it is not until regular use of drugs resulting in negative consequences (problem use) that the teen is identified as having a problem, either by parents, friends, teachers, or a healthcare provider. Certain protective factors play a part in buffering the risk factors as well as assisting in anticipating the long-term outcome of experimentation. Having emotionally supportive parents with open communication styles, involvement in organized school activities, having mentors or role models outside the home, and recognition of the importance of academic achievement are examples of the important protective factors.

Table 140.1

Assessing the Seriousness of Adolescent Drug Abuse

VARIABLE	0	+1	+2
Age (yr)	>15	<15	
Sex	Male	Female	
Family history of drug abuse		Yes	

Setting of drug use	In group		Alone
Affect before drug use	Happy	Always poor	Sad
School performance	Good, improving		Recently poor
Use before driving	None		Yes
History of accidents	None		Yes
Time of week	Weekend	Weekdays	
Time of day		After school	Before or during school
Type of drug	Marijuana, beer, wine	Hallucinogens, amphetamines	Whiskey, opiates, cocaine, barbiturates

Total score: 0-3, less worrisome; 3-8, serious; 8-18, very serious.

Table 140.2

Stages of Adolescent Substance Abuse

STAGE	DESCRIPTION
1	Potential for abuse • Decreased impulse control • Need for immediate gratification • Available drugs, alcohol, inhalants • Need for peer acceptance
2	Experimentation: learning the euphoria • Use of inhalants, tobacco, marijuana, and alcohol with friends • Few, if any, consequences • Use may increase to weekends regularly • Little change in behavior
3	Regular use: seeking the euphoria • Use of other drugs, e.g., stimulants, LSD, sedatives • Behavioral changes and some consequences • Increased frequency of use; use alone • Buying or stealing drugs
4	Regular use: preoccupation with the “high” • Daily use of drugs • Loss of control • Multiple consequences and risk taking • Estrangement from family and “straight” friends
5	Burnout: use of drugs to feel normal • Polysubstance use/cross-addiction • Guilt, withdrawal, shame, remorse, depression • Physical and mental deterioration • Increased risk taking, self-destructive, suicidal

Epidemiology

Alcohol, cigarettes, and marijuana are the most commonly reported substances used among U.S. teens (Table 140.3). The prevalence of substance use and associated risky behaviors vary by age, gender, race/ethnicity, and other sociodemographic factors. Younger teenagers tend to report less use of drugs than do older teenagers, except for inhalants (in 2016, 4.4% in 8th grade, 2.8% in 10th grade, 1.0% in 12th grade). Males have higher rates of both licit and illicit drug use than females, with greatest differences seen in their higher rates of frequent use of smokeless tobacco, cigars, and anabolic steroids. For a number of years, black 12th graders have reported lifetime, annual, 30-day, and daily prevalence levels for nearly all drugs that were lower than those for white or Hispanic 12th graders. That is less true today, with levels of drug use among blacks more similar to the other groups.

[a] The proportional change is the percent by which the most recent year deviates from the peak year (or the low year) for the drug in question. Thus, if a drug was at 20% prevalence in the peak year and declined to 10% prevalence in the most recent year, this would reflect a proportional decline of 50%.

[b] Question was discontinued among 8th and 10th graders in 2012.

[c] In 2013, for the questions on the use of amphetamines, the text was changed on 2 of the questionnaire forms for 8th and 10th graders and 4 of the questionnaire forms for 12th graders. This change also impacted the any illicit drug indices. Data presented here include only the changed forms beginning in 2013.

[d] In 2014, the text was changed on 1 of the questionnaire forms for 8th, 10th, and 12th graders to include “Molly” in the description. The remaining forms were changed in 2015. Data for both versions of the question are presented here.

Notes: "—" indicates data not available; "‡ " indicates a change in the question text. When a question change occurs, peak levels after that change are used to calculate the peak year to current year difference.

Values in **bold** equal peak levels since 1991. Values in *italics* equal peak level before wording change. Underlined values equal lowest level since recent peak level.

Level of significance of difference between classes: s = .05, ss = .01, sss = .001.

Any apparent inconsistency between the change estimate and the prevalence estimates for the 2 most recent years is caused by rounding.

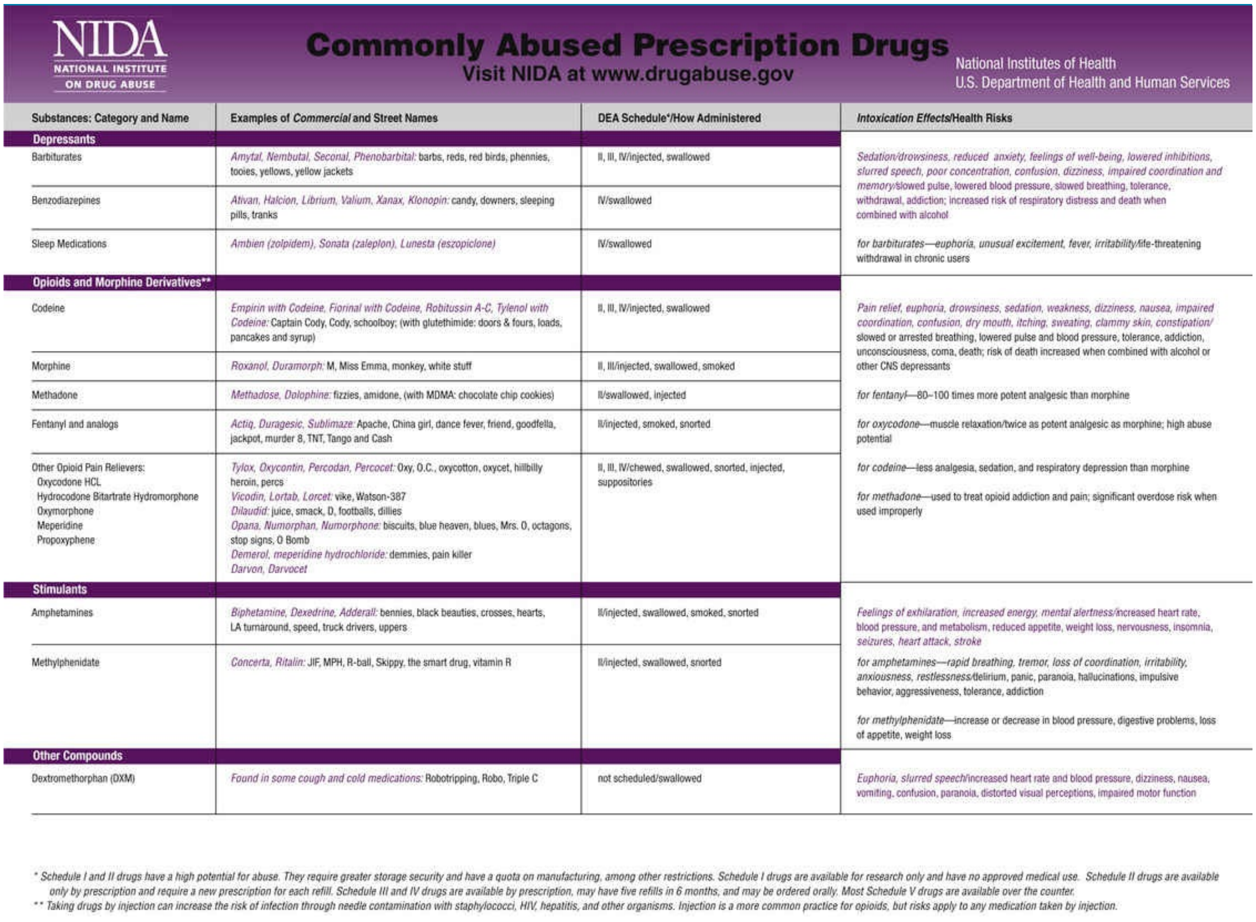
From Johnston LD, Miech RA, O'Malley PM, et al: Monitoring the Future national survey results on drug use: 1975–2017. Overview, key findings on adolescent drug use. Ann Arbor, 2018, Institute for Social Research, University of Michigan. http://www.monitoringthefuture.org//pubs/monographs/mtf-overview2017.pdf .

The distribution of annual marijuana use by race/ethnicity varies by grade level. In all 3 grades, prevalence is highest among Hispanic students. Differences in prevalence across the groups are proportionately largest in 8th grade (13% for Hispanics, 7.8% for whites), somewhat smaller in 10th grade (27% for Hispanics, 24% for whites), and negligible in 12th grade (37% for Hispanics, 35% for whites). Blacks fall between whites and Hispanics in 8th and 10th grade but are slightly below them in 12th grade (35%).

The number of 12th graders who report using any of the prescription psychotherapeutic drugs, including amphetamines, sedatives (barbiturates), tranquilizers, and narcotics other than heroin, decreased in 2016 (Table 140.4). Prevalence was 18.0%, 12.0%, and 5.4% for lifetime, annual, and 30-day use, respectively, indicating that a substantial portion of adolescents still use prescription drugs nonmedically. Rural adolescents were 26% more likely than urban adolescents to have used prescription drugs nonmedically. Use was associated with decreased health status, major depressive episode(s), and other drug use (marijuana, cocaine, hallucinogens, inhalants) and alcohol use. In a large-scale study of 16,209 adolescent exposures to prescription drugs, 52.4% were females, and the mean age was 16.6 yr. The 5 most frequently misused or abused drugs were hydrocodone (32%), amphetamines (18%), oxycodone (15%), methylphenidate (14%), and tramadol (11%). Many of these drugs can be found in the parents' home, some are over-the-counter (OTC) drugs (dextromethorphan, pseudoephedrine), whereas others are purchased from drug dealers at schools and colleges. Teen users of nonmedical opioids use other substances concurrently. Most frequently, teens combine opioids with marijuana, alcohol, cocaine, and tranquilizers, putting them at risk for serious complications and overdose.

Table 140.4

Commonly Abused Prescription Drugs



NIDA
NATIONAL INSTITUTE ON DRUG ABUSE

Commonly Abused Prescription Drugs
Visit NIDA at www.drugabuse.gov

National Institutes of Health
U.S. Department of Health and Human Services

Substances: Category and Name	Examples of *Commercial* and Street Names	DEA Schedule*/How Administered	*Intoxication Effects*/Health Risks
Depressants			
Barbiturates	*Amytal, Nembutal, Seconal, Phenobarbital:* barbs, reds, red birds, phennies, tooies, yellows, yellow jackets	II, III, IV/injected, swallowed	*Sedation/drowsiness, reduced anxiety, feelings of well-being, lowered inhibitions, slurred speech, poor concentration, confusion, dizziness, impaired coordination and memory*/slowed pulse, lowered blood pressure, slowed breathing, tolerance, withdrawal, addiction; increased risk of respiratory distress and death when combined with alcohol *for barbiturates—euphoria, unusual excitement, fever, irritability*/life-threatening withdrawal in chronic users
Benzodiazepines	*Ativan, Halcion, Librium, Valium, Xanax, Klonopin:* candy, downers, sleeping pills, tranks	IV/swallowed	
Sleep Medications	*Ambien (zolpidem), Sonata (zaleplon), Lunesta (eszopiclone)*	IV/swallowed	
Opioids and Morphine Derivatives**			
Codeine	*Empirin with Codeine, Fiorinal with Codeine, Robitussin A-C, Tylenol with Codeine:* Captain Cody, Cody, schoolboy; (with glutethimide: doors & fours, loads, pancakes and syrup)	II, III, IV/injected, swallowed	*Pain relief, euphoria, drowsiness, sedation, weakness, dizziness, nausea, impaired coordination, confusion, dry mouth, itching, sweating, clammy skin, constipation*/slowed or arrested breathing, lowered pulse and blood pressure, tolerance, addiction, unconsciousness, coma, death; risk of death increased when combined with alcohol or other CNS depressants *for fentanyl*—80–100 times more potent analgesic than morphine *for oxycodone*—muscle relaxation/twice as potent analgesic as morphine; high abuse potential *for codeine*—less analgesia, sedation, and respiratory depression than morphine *for methadone*—used to treat opioid addiction and pain; significant overdose risk when used improperly
Morphine	*Roxanol, Duramorph:* M, Miss Emma, monkey, white stuff	II, III/injected, swallowed, smoked	
Methadone	*Methadose, Dolophine:* fizzies, amidone, (with MDMA: chocolate chip cookies)	II/swallowed, injected	
Fentanyl and analogs	*Actiq, Duragesic, Sublimaze:* Apache, China girl, dance fever, friend, goodfella, jackpot, murder 8, TNT, Tango and Cash	II/injected, smoked, snorted	
Other Opioid Pain Relievers: Oxycodone HCL Hydrocodone Bitartrate Hydromorphone Oxymorphone Meperidine Propoxyphene	*Tylox, Oxycontin, Percodan, Percocet:* Oxy, O.C., oxycotton, oxycet, hillbilly heroin, percs *Vicodin, Lortab, Lorcet:* vike, Watson-387 *Dilaudid:* juice, smack, D, footballs, dillies *Opana, Numorphan, Numorphone:* biscuits, blue heaven, blues, Mrs. O, octagons, stop signs, O Bomb *Demerol, meperidine hydrochloride:* demmies, pain killer *Darvon, Darvocet*	II, III, IV/chewed, swallowed, snorted, injected, suppositories	
Stimulants			
Amphetamines	*Biphetamine, Dexedrine, Adderall:* bennies, black beauties, crosses, hearts, LA turnaround, speed, truck drivers, uppers	II/injected, swallowed, smoked, snorted	*Feelings of exhilaration, increased energy, mental alertness*/increased heart rate, blood pressure, and metabolism, reduced appetite, weight loss, nervousness, insomnia, *seizures, heart attack, stroke* *for amphetamines—rapid breathing, tremor, loss of coordination, irritability, anxiousness, restlessness*/delirium, panic, paranoia, hallucinations, impulsive behavior, aggressiveness, tolerance, addiction *for methylphenidate*—increase or decrease in blood pressure, digestive problems, loss of appetite, weight loss
Methylphenidate	*Concerta, Ritalin:* JIF, MPH, R-ball, Skippy, the smart drug, vitamin R	II/injected, swallowed, snorted	
Other Compounds			
Dextromethorphan (DXM)	*Found in some cough and cold medications:* Robotripping, Robo, Triple C	not scheduled/swallowed	*Euphoria, slurred speech*/increased heart rate and blood pressure, dizziness, nausea, vomiting, confusion, paranoia, distorted visual perceptions, impaired motor function

* *Schedule I and II drugs have a high potential for abuse. They require greater storage security and have a quota on manufacturing, among other restrictions. Schedule I drugs are available for research only and have no approved medical use. Schedule II drugs are available only by prescription and require a new prescription for each refill. Schedule III and IV drugs are available by prescription, may have five refills in 6 months, and may be ordered orally. Most Schedule V drugs are available over the counter.*

** *Taking drugs by injection can increase the risk of infection through needle contamination with staphylococci, HIV, hepatitis, and other organisms. Injection is a more common practice for opioids, but risks apply to any medication taken by injection.*

Clinical Manifestations

Although manifestations vary by the specific substance of use, adolescents who use drugs often present in an office setting with no obvious physical findings. Drug use is more frequently detected in adolescents who experience trauma such as motor vehicle crashes, bicycle injuries, or violence. Eliciting appropriate historical information regarding substance use, followed by blood alcohol and urine drug screens, is recommended in emergency settings. Although waning in popularity, the illicit substances known as “club drugs” still need to be considered in the differential diagnosis of a teen with an altered sensorium (Table 140.5). An adolescent presenting to an emergency setting with an impaired sensorium should be evaluated for substance use as a part of the differential diagnosis (Table 140.6). Screening for substance use is recommended for patients with psychiatric and behavioral diagnoses. Other clinical manifestations of substance use are associated with the route of use; intravenous drug use is associated with venous “tracks” and needle marks, and nasal mucosal injuries are associated with nasal insufflation of drugs. Seizures can be a direct effect of drugs such as cocaine, synthetic marijuana, and amphetamines or an effect of drug withdrawal in the case of barbiturates or tranquilizers.

Table 140.5

Common Names and Salient Features of Club Drugs Used Recreationally

Table 140.6

Most Common Toxic Syndromes

ANTICHOLINERGIC SYNDROMES	
Common signs	Delirium with mumbling speech, tachycardia, dry, flushed skin, dilated pupils, myoclonus, slightly elevated temperature, urinary retention, and decreased bowel sounds. Seizures and dysrhythmias may occur in severe cases.
Common causes	Antihistamines, antiparkinsonian medication, atropine, scopolamine, amantadine, antipsychotic agents, antidepressant agents, antispasmodic agents, mydriatic agents, skeletal muscle relaxants, and many plants (notably jimsonweed and *Amanita muscaria*).
SYMPATHOMIMETIC SYNDROMES	
Common signs	Delusions, paranoia, tachycardia (or bradycardia if the drug is a pure α-adrenergic agonist), hypertension, hyperpyrexia, diaphoresis, piloerection, mydriasis, and hyperreflexia. Seizures, hypotension, and dysrhythmias may occur in severe cases.
Common causes	Cocaine, amphetamine, methamphetamine (and its derivatives 3,4-methylenedioxyamphetamine, 3,4-methylenedioxymethamphetamine, 3,4-methylenedioxyethamphetamine, and 2,5-dimethoxy-4-bromoamphetamine), some synthetic marijuana, and OTC decongestants (phenylpropanolamine, ephedrine, and pseudoephedrine). In caffeine and theophylline overdoses, similar findings, except for the organic psychiatric signs, result from catecholamine release.
OPIATE, SEDATIVE, OR ETHANOL INTOXICATION	
Common signs	Coma, respiratory depression, miosis, hypotension, bradycardia, hypothermia, pulmonary edema, decreased bowel sounds, hyporeflexia, and needle marks. Seizures may occur after overdoses of some narcotics, notably propoxyphene.
Common causes	Narcotics, barbiturates, benzodiazepines, ethchlorvynol, glutethimide, methyprylon, methaqualone, meprobamate, ethanol, clonidine, and guanabenz.
CHOLINERGIC SYNDROMES	
Common signs	Confusion, central nervous system depression, weakness, salivation, lacrimation, urinary and fecal incontinence, gastrointestinal cramping, emesis, diaphoresis, muscle fasciculations, pulmonary edema, miosis, bradycardia or tachycardia, and seizures.
Common causes	Organophosphate and carbamate insecticides, physostigmine, edrophonium, and some mushrooms.

Screening for Substance Abuse Disorders

In a primary care setting the annual health maintenance examination provides an opportunity for identifying adolescents with substance use or abuse issues. The direct questions as well as the assessment of school performance, family relationships, and peer activities may necessitate a more in-depth interview if there are suggestions of difficulties in those areas. Several self-report screening questionnaires also are available, with varying degrees of standardization, length, and reliability. The **CRAFFT mnemonic** is specifically designed to screen for adolescents' substance use in the primary setting (Table 140.7). Privacy and confidentiality must be established when asking the teen about specifics of their substance experimentation or use. Interviewing the parents can provide additional perspective on early warning signs that go unnoticed or disregarded by the teen. Examples of early warning signs of teen substance use are change in mood, appetite, or sleep pattern; decreased interest in school or school performance; loss of weight; secretive behavior about social plans; or valuables such as money or jewelry missing from the home. The use of urine drug screening is recommended when select circumstances are present: (1) psychiatric symptoms to rule out comorbidity or dual diagnoses, (2) significant changes in school performance or other daily behaviors, (3) frequently occurring accidents, (4) frequently occurring episodes of respiratory problems, (5) evaluation of serious motor vehicular or other injuries, and (6) as a monitoring procedure for a recovery program. Table 140.8 shows common tests used for detection by substance, along with the approximate retention time between use and identification in the urine. Most initial screening uses an immunoassay method, such as the enzyme-multiplied immunoassay technique, followed by a confirmatory test using highly sensitive, highly specific gas chromatography–mass spectrometry. The substances that can cause false-positive results should be considered, especially when there is a discrepancy between the physical findings and the urine drug screen result. In 2007 the American of Academy of Pediatrics (AAP) released guidelines that strongly discourage routine home-based or school-based testing.

Table 140.7

CRAFFT Mnemonic Tool

- Have you ever ridden in a **C** ar driven by someone (including yourself) who was high or had been using alcohol or drugs?
- Do you ever use alcohol or drugs to **R** elax, feel better about yourself or fit in?
- Do you ever use alcohol or drugs while you are by yourself (**A** lone)?
- Do you ever **F** orget things you did while using alcohol or drugs?
- Do your Family or **F** riends ever tell you that you should cut down on your drinking or drug use?
- Have you ever gotten into **T** rouble while you were using alcohol or drugs?

Codeine	Morphine	IA	TLC	GC, GC/MS	2 days
	Glucuronide				

Phencyclidine		TLC	IA	GC, GC/MS	8 days

GC, Gas chromatography; IA, immunoassay; MS, mass spectrometry; TLC, thin-layer chromatography.

Modified from Drugs of abuse—urine screening [physician information sheet], Los Angeles, Pacific Toxicology. From MacKenzie RG, Kipke MD: Substance use and abuse. In Friedman SB, Fisher M, Schonberg SK, editors: *Comprehensive adolescent health care,* St Louis, 1998, Mosby.

Diagnosis

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) no longer identifies substance use disorders as those of *abuse* or of *dependence* . A substance use disorder is defined by a cluster of cognitive, behavioral, and physiologic symptoms that indicate that an adolescent is using a substance even though there is evidence that the substance is harming the adolescent. Even after detoxification, a substance use disorder may leave persisting changes in brain circuits with resulting behavioral changes. There are 11 criteria that describe a pathologic pattern of behaviors related to use of the substance, falling into 4 categories: impaired control, social impairment, increased risk, and pharmacologic criteria. The 1st category, **impaired control** , describes an individual taking increasing amounts of the substance who expresses a persistent desire to decrease use, with unsuccessful efforts. The individual may spend a great deal of time obtaining the substance, using the substance, or recovering from its effects and expresses an intense desire for the drug, usually in settings where the drug had been available, such as a specific type of social situation. The 2nd cluster of criteria (5-7) reflects **social impairment,** including the inability to perform as expected in school, at home, or at a job; increasing social problems; and withdrawing from the family. The 3rd cluster of 2 criteria addresses **increased risk** associated with use of the substance, and the 4th cluster includes 2 criteria addressing **pharmacologic responses** (tolerance and/or withdrawal). The total number of criteria present is associated with a determination of a *mild, moderate,* or *severe* disorder.

These criteria may have limitations with adolescents because of differing patterns of use, developmental implications, and other age-related consequences. Adolescents who meet diagnostic criteria should be referred to a program for substance use disorder treatment unless the primary care physician has additional training in addiction medicine.

Complications

Substance use in adolescence is associated with comorbidities and acts of juvenile delinquency. Youth may engage in other high-risk behaviors such as robbery, burglary, drug dealing, or prostitution for the purpose of acquiring the money necessary to buy drugs or alcohol. Regular use of any drug eventually diminishes judgment and is associated with unprotected sexual activity with its consequences of pregnancy and sexually transmitted infections, including HIV, as well as physical violence and trauma. Drug and alcohol use is closely associated with trauma in the adolescent population. Several studies of adolescent trauma victims have identified cannabinoids and cocaine in blood and urine samples in significant proportions (40%), in addition to the more common identification of alcohol. Any use of injected substances involves the risk of hepatitis B and C viruses as well as HIV (see Chapter 302).

Treatment

Adolescent drug abuse is a complex condition requiring a multidisciplinary approach that attends to the needs of the individual, not just drug use. Fundamental principles for treatment include accessibility to treatment; utilizing a multidisciplinary approach; employing individual or group counseling; offering mental health services; monitoring of drug use while in treatment; and understanding that recovery from drug abuse/addiction may involve multiple relapses. For most patients, remaining in treatment for a minimum period of 3 mo will result in a significant improvement.

Prognosis

For adolescent substance abusers who have been referred to a drug treatment program, positive outcomes are directly related to regular attendance in posttreatment groups. For males with learning problems or conduct disorder, outcomes are poorer than for those without such disorders. Peer use patterns and parental use have a major influence on outcome for males. For females, factors such as self-esteem and anxiety are more important influences on outcomes. The chronicity of a substance use disorder makes **relapse** an issue that must always be considered when managing patients after treatment, and appropriate assistance from a health professional qualified in substance abuse management should be obtained.

Prevention

Preventing drug use among children and teens requires prevention efforts aimed at the individual, family, school, and community levels. The National Institute on Drug Abuse (NIDA) of the U.S. National Institutes of Health has identified essential principles of successful prevention programs. Programs should enhance *protective factors* (parent support) and reduce *risk factors* (poor self-control); should address all forms of drug abuse (legal and illegal); should address the specific type(s) of drug abuse within an identified community; and should be culturally competent to improve effectiveness (Table 140.9). The highest-risk periods for substance use in children and adolescents are during life transitions, such as the move from elementary school to middle school, or from middle school to high school. Prevention programs need to target these emotionally and socially intense times for teens to adequately anticipate potential substance use or abuse. Examples of effective research-based drug abuse prevention programs featuring a variety of strategies are listed on the NIDA website (www.drugabuse.gov), and on the Center for Substance Abuse Prevention website (www.prevention.samhsa.gov).

Table 140.9

Domains of Risk and Protective Factors for Substance Abuse Prevention

RISK FACTORS	DOMAIN	PROTECTIVE FACTORS
Early aggressive behavior	Individual	Self-control
Lack of parental supervision	Family	Parental monitoring
Substance abuse	Peer	Academic competence
Drug availability	School	Anti–drug use policies
Poverty	Community	Strong neighborhood attachment

From National Institute on Drug Abuse: *Preventing drug use among children and adolescents: a research-based guide for parents, educators, and community leaders,* NIH Pub No 04-4212(B), ed 2, Bethesda, MD, 2003, NIDA.

140.1

Alcohol

Cora Collette Breuner

Alcohol is the most widely used substance of abuse among America's youth, and a higher proportion use alcohol than use tobacco or other drugs, but the numbers are trending down. According to the 2016 **Monitoring the Future (MTF)** study, 19.9% (down from 27.6%) of 10th graders reported using alcohol in the past 30 days. Early initiation of alcohol use increases the risk for a variety of developmental problems during adolescence and is frequently an indicator of future substance use. Drinking by children, adolescents, and young adults has serious negative consequences for the individuals, their families, their communities, and society as a whole. Underage drinking contributes to a wide range of costly health and social problems, including motor vehicle crashes (the greatest single mortality risk for underage drinkers); suicide; interpersonal violence (e.g., homicides, assaults, rapes); unintentional injuries such as burns, falls, and drowning; brain impairment; alcohol dependence; risky sexual activity; academic problems; and alcohol and drug poisoning. On average, alcohol is a factor in the deaths of approximately 4,300 youths in the United States per year, shortening their life by an average of 60 yr.

According to the Centers for Disease Control and Prevention (CDC) 2015 Youth Risk Behavior Survey (YRBS), 63.2% of students had had at least 1 drink of alcohol on at least 1 day during their life (i.e., ever drank alcohol). The prevalence of having ever drunk alcohol was higher among female (65.3%) than male (61.4%) students; higher among black female (57.9%) and Hispanic female (68.6%) than black male (51.0%) and Hispanic male (63.4%) students, respectively; and higher among female (53.0%) than male (48.9%) 9th graders.

The prevalence of having ever drunk alcohol was higher among white (65.3%) and Hispanic (65.9%) than black (54.4%) students, higher among white female (66.7%) and Hispanic female (68.6%) than black female (57.9%) students, and higher among white male (64.0%) and Hispanic male (63.4%) than black male (51.0%) students.

The prevalence of having ever drunk alcohol was higher among 10th graders (60.8%), 11th graders (70.3%), and 12th graders (73.3%) than 9th graders

(50.8%); higher among 11th-grade female (72.1%) and 12th-grade female (75.2%) than 9th-grade female (53.0%) and higher among 10th-grade male (58.8%), 11th-grade male (68.7%), and 12th-grade male (71.5%) than 9th-grade male (48.9%) students.

Multiple factors can affect a young teen's risk of developing a drinking problem at an early age (Table 140.10). One third of high school seniors admit to combining drinking behaviors with other risky behaviors, such as driving or taking additional substances. **Binge drinking** remains especially problematic among the older teens and young adults; 31% of high school seniors report having 5 or more drinks in a row in the last 30 days. Higher use is seen in males (23.8%) than in females (19.8%), and whites (24.0%) and Hispanics (24.2%) than in blacks (12.4%). Teens with binge-drinking patterns are more likely to be assaulted, engage in high-risk sexual behaviors, have academic problems, and be injured than those teens without binge drinking patterns.

Table 140.10

Risk Factors for a Teen Developing a Drinking Problem

Family Risk Factors

- Low parental supervision
- Poor parent to teen communication
- Family conflicts
- Severe or inconsistent family discipline
- Having a parent with an alcohol or drug problem

Individual Risk Factors

- Poor impulse control
- Emotional instability
- Thrill-seeking behaviors
- Behavioral problems
- Perceived risk of drinking is low
- Begins drinking before age 14 yr

Alcohol contributes to more **deaths** in young individuals in the United States than all the illicit drugs combined. Among studies of adolescent trauma victims, alcohol is reported to be present in 32–45% of hospital admissions. Motor vehicle crashes are the most frequent type of event associated with alcohol use, but the injuries spanned several types, including self-inflicted wounds.

Alcohol is often mixed with energy drinks (caffeine, taurine, sugars), which can result in a spectrum of alcohol-related negative behaviors. **Caffeine** may counter the sedative effects of alcohol, resulting in more alcohol consumption and a perception of not being intoxicated, thus leading to risk-taking behavior such as driving while intoxicated. In addition, aggressive behavior, including sexual assaults and motor vehicle or other injuries, has been reported. Both alcohol and caffeine overdoses have also been reported.

Pharmacology and Pathophysiology

Alcohol (ethyl alcohol or ethanol) is rapidly absorbed in the stomach and is transported to the liver and metabolized by 2 pathways. The primary metabolic pathway contributes to the excess synthesis of triglycerides, a phenomenon that is responsible for producing a **fatty liver** , even in those who are well nourished. Engorgement of hepatocytes with fat causes necrosis, triggering an inflammatory process (**alcoholic hepatitis**), later followed by fibrosis, the hallmark of **cirrhosis** . Early hepatic involvement may result in elevation in γ-glutamyltransferase (GGT) and serum glutamic-pyruvic transaminase (alanine transaminase). The 2nd metabolic pathway, which is utilized at high serum alcohol levels, involves the microsomal enzyme system of the liver, in which the cofactor is reduced nicotinamide-adenine dinucleotide phosphate. The net effect of activation of this pathway is to decrease metabolism of drugs that share this system and to allow for their accumulation, enhanced effect, and possible toxicity.

Clinical Manifestations

Alcohol acts primarily as a central nervous system (CNS) depressant. It produces euphoria, grogginess, talkativeness, impaired short-term memory, and an increased pain threshold. Alcohol's ability to produce vasodilation and hypothermia is also centrally mediated. At very high serum levels, respiratory depression occurs. Its inhibitory effect on pituitary antidiuretic hormone release is responsible for its diuretic effect. The gastrointestinal (GI) complications of alcohol use can occur from a single large ingestion. The most common is acute **erosive gastritis** , manifesting as epigastric pain, anorexia, vomiting, and heme-positive stools. Less frequently, vomiting and mid-abdominal pain may be caused by acute alcoholic **pancreatitis** ; diagnosis is confirmed by the finding of elevated serum amylase and lipase levels.

Diagnosis

Primary care settings provide the opportunity to screen teens for alcohol use or problem behaviors. Brief alcohol screening instruments such as CRAFFT (see Table 140.7) or AUDIT (Alcohol Use Disorders Identification Test, Table 140.11) perform well in a clinical setting as techniques to identify alcohol use disorders. A score of ≥8 on the AUDIT questionnaire identifies people who drink excessively and who would benefit from reducing or ceasing drinking. Teenagers in the early phases of alcohol use exhibit few physical findings. Recent use of alcohol may be reflected in elevated GGT and aspartate transaminase levels.

Table 140.11

Alcohol Use Disorders Identification Test (AUDIT)

	SCORE (0-4)*
1. How often do you have a drink containing alcohol?	Never (0) to more than 4 per wk (4)
2. How many drinks containing alcohol do you have on a typical day?	One or 2 (0) to more than 10 (4)
3. How often do you have 6 or more drinks on 1 occasion?	Never (0) to daily or almost daily (4)
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never (0) to daily or almost daily (4)
5. How often during the last year have you failed to do what was normally expected from you because of drinking?	Never (0) to daily or almost daily (4)
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never (0) to daily or almost daily (4)
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never (0) to daily or almost daily (4)
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?	Never (0) to daily or almost daily (4)
9. Have you or someone else been injured as a result of your drinking?	No (0) to yes, during the last year (4)
10. Has a relative, friend, doctor or other health worker been concerned about your drinking or suggested that you should cut down?	No (0) to yes, during the last year (4)

[*] Score ≥8 = problem drinking.

From Schuckit MA: Alcohol-use disorders, *Lancet* 373:492–500, 2009.

In acute care settings the **alcohol overdose syndrome** should be suspected in any teenager who appears disoriented, lethargic, or comatose. Although the distinctive aroma of alcohol may assist in diagnosis, confirmation by analysis of blood is recommended. At levels >200 mg/dL, the adolescent is at risk of death, and levels >500 mg/dL (median lethal dose) are usually associated with a fatal outcome. When the level of obtundation appears excessive for the reported blood alcohol level, head trauma, hypoglycemia, or ingestion of other drugs should be considered as possible confounding factors.

Treatment

The usual mechanism of death from the alcohol overdose syndrome is **respiratory depression** , and artificial ventilatory support must be provided until the liver can eliminate sufficient amounts of alcohol from the body. In a patient without alcoholism, it generally takes 20 hr to reduce the blood level of alcohol from 400 mg/dL to zero. Dialysis should be considered when the blood level is >400 mg/dL. As a follow-up to acute treatment, referral for treatment of the alcohol use disorder is indicated. Group counseling, individualized counseling, and multifamily educational intervention have proved to be effective interventions for teens.

Cigarettes

Tobacco use and addiction almost always start in childhood or adolescence, a period when the brain has heightened susceptibility to nicotine addiction. Nearly 90% of adult smokers began smoking before age 18. Factors associated with youth tobacco use include exposure to smokers (friends, parents), tobacco availability, low socioeconomic status, poor school performance, low self-esteem, lack of perceived risk of use, and lack of skills to resist influences to use tobacco.

From 2011–2017, among all US high school students, current use of cigarettes decreased from 15.8% to 7.6%. During the same time period, however, current use of e-cigarettes and hookah (water pipes used to smoke tobacco) increased significantly among middle and high school students. In 2017, e-cigarettes (11.7%) were the most commonly used tobacco product among high school students. Cigars (7.7%) and cigarettes (7.6%) were the second and third most commonly used tobacco products among high school students, followed by smokeless tobacco (5.5%), hookah (3.3%), and pipe tobacco (0.8%).

Tobacco use is associated with other high-risk behaviors. Teens who smoke are more likely than nonsmokers to use alcohol and engage in unprotected sex, are 8 times more likely to use marijuana, and are 22 times more likely to use cocaine.

Tobacco is used by teens in all regions of the world, although the form of tobacco used differs. In the Americas and Europe, cigarette smoking is the predominant form of tobacco use, followed by cigars and smokeless tobacco; in the Eastern Mediterranean, hookah use is prevalent; in Southeast Asia, smokeless tobacco products are used; in the Western Pacific, betel nut is chewed with tobacco; and pipe, snuff, and rolled tobacco leaves are used in Africa. Cigarette use by teens in low- and middle-income nations is increasing.

Pharmacology

Nicotine , the primary active ingredient in cigarettes, is addictive. Nicotine is absorbed by multiple sites in the body, including the lungs, skin, GI tract, and buccal and nasal mucosa. The action of nicotine is mediated through nicotinic acetylcholine receptors located on noncholinergic presynaptic and postsynaptic sites in the brain and causes increased levels of dopamine. Nicotine also stimulates the adrenal glands to release epinephrine, causing an immediate elevation in blood pressure, respiration, and heart rate. The dose of nicotine delivered to the user in a cigarette depends on a variety of factors, including puffing characteristics. A smoker typically takes 10 puffs within the span of 5 minutes and absorbs 1-2 mg of nicotine (range: 0.5–3 mg). **Cotinine,** the major metabolite of nicotine, has a biologic half-life of 19-24 hr and can be detected in urine, serum, and saliva.

Clinical Manifestations

Cigarettes are addictive by design and result in life-shortening diseases in half their long-term users. Each year, approximately 480,000 deaths are attributable to smoking, responsible for 1 of every 5 deaths and 1 of every 3 cancer deaths in the United States. Cigarette smoking has severe adverse health consequences for youth and young adults, including increased prevalence of chronic cough, sputum production, wheezing, and worsening asthma. Smoking during pregnancy increases prenatal and perinatal morbidity and mortality, either causing or exacerbating the risks of preterm birth, low birthweight, congenital malformations, stillbirth, and sudden infant death syndrome (SIDS). **Withdrawal** symptoms, including irritability, decreased concentration, increased appetite, and strong cravings for tobacco, can occur when adolescents try to quit.

Electronic Cigarettes (E-Cigarettes)

E-cigarettes, also known as **electronic nicotine delivery systems (ENDS)** , are handheld devices that produce an aerosol created from a solution of nicotine, flavoring chemicals, propylene glycol, and often other constituents unknown and unadvertised to the consumer. There is wide variability in terminology, product design, and engineering of these products, with alternative names including e-cigs, electronic cigars, electronic hookah, e-hookah, personal vaporizers, vape pens, and vaping devices. The industry continues to develop new products, such as JUUL, which contain nicotine but may not be recognized as a tobacco product by teens. The unique flavors offered in e-cigarette solution, the majority of which are confectionary in nature and appealing to children, have been shown to encourage youth experimentation, regular use, and addiction.

Adverse effects to users include dry cough, throat irritation, and lipoid pneumonia. Nonusers could be impacted by the secondhand and thirdhand aerosol (residual nicotine and other chemicals left on surfaces), which have been shown to contain known toxicants, including nicotine, carcinogens, and metal particles. Rates of acute nicotine poisoning have increased from unintentional exposure of children to the concentrated nicotine–containing e-cigarette solution. Studies of adolescents suggest a strong association between e-cigarette use at baseline and progression to traditional cigarette smoking. E-cigarettes may contribute to subsequent cigarette use through nicotine addiction and social normalization of smoking behaviors.

E-cigarettes are not U.S. Food and Drug Administration (FDA) approved and have not been shown to be safe or effective for smoking cessation treatment. Unless the quality of the evidence improves, adolescent smokers interested in quitting should seek and be referred to evidence-based treatments. In August 2016 the FDA finalized a rule that extends its regulatory authority to all tobacco products, including e-cigarettes, affecting how these products are manufactured, marketed, and sold. It requires manufacturers to report product ingredients and undergo the agency's premarket review to receive marketing authorization. In 2017, however, the FDA delayed implementation of this rule until 2022, allowing e-cigarettes (as of April 2019) to remain on the market without premarket review.

Hookah

Hookah (water pipe) smoking uses specially treated tobacco that comes in a variety of flavors. Emerging evidence indicates that hookah may involve comparable health risks to cigarettes, including nicotine dependence. Both human and machine simulation studies of hookah use consistently find that smoke content and user toxicant exposure, including carbon monoxide, tar, and nicotine, are at least comparable to that of cigarettes. Secondhand smoke from hookahs can be a health risk for nonsmokers exposed to harmful toxicants.

Treatment

Tobacco prevention interventions delivered in pediatric settings, including individual encounters or connection to educational materials, can reduce the risk for smoking initiation in school-age children and adolescents. Messages should be clear, personally relevant, and age appropriate. Adolescents may be more responsive to messages that emphasize the effects of tobacco use on appearance, breath, and sports performance; lack of benefit for weight loss; monetary cost of tobacco addiction; and deceptive marketing by the tobacco industry.

The approach to smoking cessation in adolescents includes the **5 A** s **(ask, advise, assess, assist,** and **arrange)** and use of **nicotine replacement therapy (NRT)** in addicted teens who are motivated to quit. Consensus panels recommend the 5 As, although evidence of efficacy in adolescents is limited. Studies of the NRT patch in adolescents suggest a positive effect on reducing withdrawal symptoms; pharmacotherapy should be combined with behavioral therapy to increase cessation and lower relapse rates. In a limited number of studies, cessation rates of 15% were reported at 3 and 6 mo. NRT is also available as a gum, inhaler, nasal spray, lozenge, or microtab (Table 140.12). Medications such as bupropion and varenicline improve smoking cessation rates in adults but are not FDA approved for use in adolescents <18 yr old. Preliminary studies in adolescents report cessation efficacy with 150 mg of bupropion twice daily. In postmarketing surveillance, suicidal ideation and suicide have been reported among patients taking bupropion and varenicline.

Table 140.12

Smoking Cessation Pharmacotherapy Available in the United States

THERAPY BRAND	NAME	STRENGTHS	FDA-APPROVED ADULT DOSING	AVAILABILITY*	STUDIED IN ADOLESCENTS	QUIT DATE
NICOTINE REPLACEMENT THERAPY						
Gum ‡	Nicorette	2 mg, 4 mg	The 4-mg strength should be used by patients who smoke ≥25 cigarettes a day; otherwise, 2-mg strength should be used. Wk 1-6: 1 piece every	OTC*	Yes	

			1-2 hr Wk 7-9: 1 piece every 2-4 hr Wk 10-12: 1 piece every 4-8 hr			
Inhaler	Nicotrol Inhaler	4 mg	6-16 cartridges a day for up to 12 wk	Rx	No	
Lozenge	Commit, Nicorette mini	2 mg, 4 mg	The 4-mg strength should be used by patients who smoke 1st cigarette within 30 min of waking; otherwise, 2-mg strength should be used. Wk 1-6: 1 lozenge every 1-2 hr Wk 7-9: 1 lozenge every 2-4 hr Wk 10-12: 1 lozenge every 4-8 hr	OTC	No	Prior to beginning nicotine replacement therapy
Nasal Spray	Nicotrol NS	0.5 mg/spray	1-2 sprays/hr up to a maximum of 80 sprays per day	Rx	Yes	
Transdermal Patch ‡	NicoDerm CQ	7, 14, 21 mg/24 hr	For patients who smoke >10 cigarettes daily: Step 1: one 21-mg patch daily for wk 1-6 Step 2: one 14-mg patch daily for wk 7-8 Step 3: one 7-mg patch daily for wk	OTC	Yes	

			9-10 For patients who smoke <10 cigarettes daily: Begin with 14-mg patch daily for 6 wk, followed by 7-mg patch for 2 wk.			
NONNICOTINE THERAPY						
Bupropion SR[‡]	Zyban	150-mg sustained-release tablets	150 mg PO in morning for 3 days, then increase to 150 mg PO bid	Rx	Yes	1 wk after starting therapy
Varenicline	Chantix	0.5-, 1-mg tablets	0.5 mg PO in morning for 3 days; increase to 0.5 mg PO bid for 4 days, then increase to 1 mg PO bid	Rx	No	

[*] OTC, Over the counter; Rx, prescription product; PO, by mouth (orally); bid, twice daily.

[‡] Generics available.

[†] None is FDA approved for use in patients younger than 18 yr.

From JP Karpinski et al: Smoking cessation treatment for adolescents, *J Pediatr Pharmacol Ther* 15(4):249–260, 2010.

Pediatric clinicians can connect patients to effective behavioral interventions, including telephone, text message, smartphone app, internet, and community-based resources. Free telephone-based treatment (1-800-QUIT-NOW) has been shown to improve smoking cessation rates. Smoke-free TXT, offered by the National Cancer Institute, engages teens to quit smoking using free, daily text messaging. Teens can sign up online (teen.smokefree.gov) or text QUIT to iQUIT (47848). A smartphone-based app, QuitSTART, helps teens track cravings, monitor moods, use cessation tips, and follow quitting attempts. The American Lung Association's **Not-On-Tobacco Program (NOT)** is a nationally recognized best-practice model for teen smoking cessation (see www.lung.org).

140.3

Marijuana

Cora Collette Breuner

Keywords

THC
synthetic marijuana

Marijuana (cannabis, pot, weed, hash, grass), derived from the *Cannabis sativa* hemp plant, is the most commonly abused illicit drug. The main active chemical, tetrahydrocannabinol (**THC**), is responsible for its hallucinogenic properties. THC is absorbed rapidly by the nasal or oral routes, producing a peak of subjective effect at 10 min and 1 hr, respectively. Marijuana is generally smoked as a cigarette (reefer, joint) or in a pipe. Although there is much variation in content, each cigarette contains 8–10% THC. Another popular form that is smoked, a “blunt,” is a hollowed-out small cigar refilled with marijuana. Marijuana products (hash oil or leaf) can also be used in some vaping devices or hookah pens. **Hashish** is the concentrated THC resin in a sticky black liquid or oil. Although marijuana use by U.S. teens has declined in the last decade, 23.1% of high school students have used marijuana at least once during the previous 30 days, and current marijuana use is highest in black males and high school seniors. About 8% of students report having tried marijuana before age 13, with a range of 4.3–18.5% across various states, indicating the need for early prevention efforts. Adolescents living in states where medical marijuana is legal report a higher use of cannabis “edibles.” It is important to recognize that as perceived harm drops, marijuana use increases (Fig. 140.4).

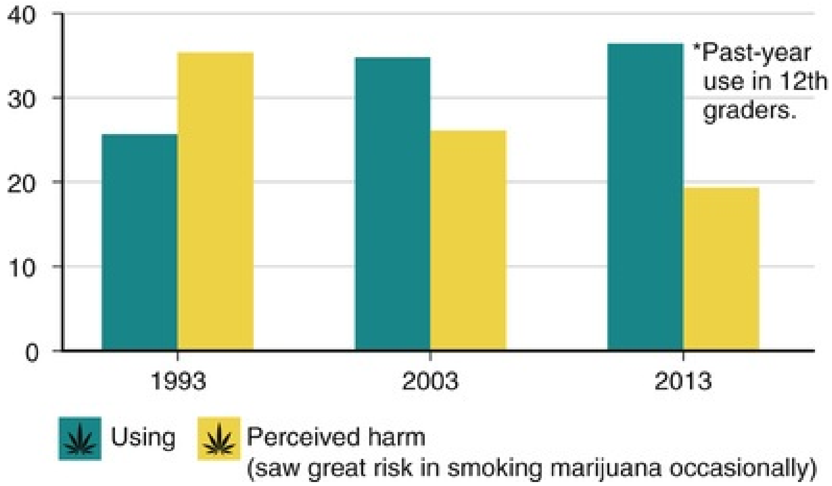

FIG. 140.4 As the perceived harm of marijuana drops, use goes up. The 36.4% using in 2013 equates to about 11 students in the average class. (From NIH National Institute on Drug Abuse.)

Clinical Manifestations

In addition to the “desired” effects of elation and euphoria, marijuana may cause impairment of short-term memory, poor performance of tasks requiring divided attention (e.g., those involved in driving), loss of critical judgment, decreased coordination, and distortion of time perception (Table 140.13). Visual hallucinations and perceived body distortions occur rarely, but “flashbacks” or recall of frightening hallucinations experienced under marijuana's influence may occur, usually during stress or with fever.

Table 140.13

Acute and Chronic Adverse Effects of Cannabis Use

Acute Adverse Effects

- Anxiety and panic, especially in naïve users

- Psychotic symptoms (at high doses)
- Road crashes if a person drives while intoxicated

Chronic Adverse Effects

- Cannabis dependence syndrome (in about 1 in 10 users)
- Chronic bronchitis and impaired respiratory function in regular smokers
- Psychotic symptoms and disorders in heavy users, especially those with a history of psychotic symptoms or a family history of these disorders
- Impaired educational attainment in adolescents who are regular users
- Subtle cognitive impairment in those who are daily users for 10 yr or more

From Hall W, Degenhardt L: Adverse health effects of non-medical cannabis use, *Lancet* 374:1383–1390, 2009.

Smoking marijuana for a minimum of 4 days/wk for 6 mo appears to result in dose-related suppression of plasma testosterone levels and spermatogenesis, prompting concern about the potential deleterious effect of smoking marijuana before completion of pubertal growth and development. There is an antiemetic effect of oral THC or smoked marijuana, often followed by appetite stimulation, which is the basis of the drug's use in patients receiving cancer chemotherapy. Although the possibility of teratogenicity has been raised because of findings in animals, there is no evidence of such effects in humans.

An **amotivational syndrome** has been described in long-term marijuana users who lose interest in age-appropriate behavior; proof of the causative relationship remains equivocal. Chronic use is associated with increased anxiety and depression, learning problems, poor job performance, hyperemesis, and respiratory problems such as pharyngitis, sinusitis, bronchitis, and asthma (see Table 140.13).

The **cannabinoid hyperemesis syndrome** is characterized by recurrent episodes of vomiting associated with abdominal pain and nausea; patients often find relief by taking a hot shower or bath. Cannabis use has been chronic (>1-2 yr) and frequent (multiple times per week). Treatment includes stopping marijuana use, antiemetics, and topical capsaicin.

The increased THC content of marijuana of 5-15–fold compared to that of the

1970s is related to the observation of a **withdrawal syndrome** , occurring 24-48 hr after discontinuing the drug. Heavy users experience malaise, irritability, agitation, insomnia, drug craving, shakiness, diaphoresis, night sweats, and GI disturbance. The symptoms peak by the 4th day and resolve in 10-14 days. Certain drugs may interact with marijuana to potentiate sedation (alcohol, diazepam) and stimulation (cocaine, amphetamines) or may be antagonistic (propranolol, phenytoin).

Behavioral interventions, including **cognitive-behavioral therapy (CBT)** and motivational incentives, have shown to be effective in treating marijuana dependency.

Synthetic Marijuana

Spice, K2, crazy clown, aroma, black mamba, blaze, dream, and funky monkey are some of the common street names for synthetic marijuana, which is a mixture of herbs or plant materials that have been sprayed with artificial chemicals similar to THC, the psychoactive ingredient in marijuana. One active group of chemicals is the **carboxamides,** which are not detected by standard assays to detect THC. In the United States the chemicals in “Spice” are designated a Schedule I controlled substance (as is marijuana) by the Drug Enforcement Administration (DEA), thereby making it illegal to sell, buy, or possess them. Nonetheless, synthetic marijuana is the 2nd most common illicit drug used by high school seniors. More than 10% of high school seniors used synthetic marijuana in the last year.

Synthetic marijuana is mainly used by smoking, or mixed with marijuana, or brewed as a tea for drinking. The chemicals in synthetic marijuana affect the same receptors as THC and produce similar effects as seen in cannabis use, such as relaxation, elevated mood, and altered perception. In addition, sympathomimetic symptoms are quite common and are the cause of significant toxicity. Symptoms of **intoxication** include vomiting, tachycardia, hypertension, hyperthermia, confusion, extreme anxiety, profuse sweating, agitation, aggression, dysphoria, hallucinations, seizures, rhabdomyolysis, dystonia, unresponsiveness, confusion, catatonia, “zombie-like” behaviors, and myocardial ischemia. In response to legislation to ban the chemicals in OTC synthetic marijuana products, manufacturers alter and substitute the chemicals in the product, keeping it on the legal market and leaving teens particularly vulnerable to potential health effects.

Synthetic marijuana are not detected by standard toxicology screening but can be identified in specialized laboratories.

140.4

Inhalants

Cora Collette Breuner

Keywords

huffing

Inhalants, found in many common household products, comprise a diverse group of volatile substances whose vapors can be inhaled to produce psychoactive effects. The practice of inhalation is popular among younger adolescents and decreases with age. Young adolescents are attracted to these substances because of their rapid action, easy availability, and low cost. Products that are abused as inhalants include *volatile solvents* (paint thinners, glue, e-cigarette solvents known as "dripping," toluene, acetone, refrigerants, gasoline, cleaning fluids, correction fluids), *aerosols* (spray paint, nitrous oxide, hair spray), *gases* (propane tanks, lighter fluid), *nitrites* ("poppers" or "video head cleaner"), and *propellants* used in whipped cream dispensers. The most popular inhalants among young adolescents are glue, shoe polish, and spray paint. The various products contain a wide range of chemicals with serious adverse health effects (Table 140.14). **Huffing** , the practice of inhaling fumes, can be accomplished using a paper bag containing a chemical-soaked cloth, spraying aerosols directly into the nose/mouth, or using a balloon, plastic bag, or soda can filled with fumes. The percentage of adolescents using inhalants has remained stable, with 5.8% of high school students reporting having ever used inhalants. Eighth and 9th graders report highest use, suggesting targeted prevention strategies for this age-group.

Table 140.14

Hazards of Chemicals Found in Commonly Abused Inhalants

Amyl nitrite, butyl nitrite (“poppers,” “video head cleaner”): sudden sniffing death syndrome, suppressed immunologic function, injury to red blood cells (interfering with oxygen supply to vital tissues)
Benzene (found in gasoline): bone marrow injury, impaired immunologic function, increased risk of leukemia, reproductive system toxicity
Butane, propane (found in lighter fluid, hair and paint sprays): sudden sniffing death syndrome via cardiac effects, serious burn injuries (because of flammability)
Freon (used as a refrigerant and aerosol propellant): sudden sniffing death syndrome, respiratory obstruction and death (from sudden cooling/cold injury to airways), liver damage
Methylene chloride (found in paint thinners and removers, degreasers): reduction of oxygen-carrying of blood, changes to the heart muscle and heartbeat
Nitrous oxide (“laughing gas”), **hexane** : death from lack of oxygen to the brain, altered perception and motor coordination, loss of sensation, limb spasms, blackouts caused by blood pressure changes, depression of heart muscle functioning
Toluene (found in gasoline, paint thinners and removers, correction fluid): brain damage (loss of brain tissue mass, impaired cognition, gait disturbance, loss of coordination, loss of equilibrium, limb spasms, hearing and vision loss), liver and kidney damage
Trichloroethylene (found in spot removers, degreasers): sudden sniffing death syndrome, cirrhosis of the liver, reproductive complications, hearing and vision damage

Clinical Manifestations

The major effects of inhalants are psychoactive (Table 140.15). The intoxication lasts only a few minutes, so a typical user will huff repeatedly over an extended period (hours) to maintain the high. The immediate effects of inhalants are similar to alcohol: euphoria, slurred speech, decreased coordination, and dizziness. **Toluene** , the main ingredient in model airplane glue and some rubber cements, causes relaxation and pleasant hallucinations for up to 2 hr. Euphoria is followed by violent excitement; coma may result from prolonged or rapid inhalation. **Volatile nitrites** , such as amyl nitrite, butyl nitrite, and related compounds marketed as room deodorizers, are used as euphoriants, enhancers of musical appreciation, and sexual enhancements among older adolescents and young adults. They may result in headaches, syncope, and lightheadedness; profound hypotension and cutaneous flushing followed by vasoconstriction and tachycardia; transiently inverted T waves and depressed ST segments on electrocardiography; methemoglobinemia; increased bronchial irritation; and increased intraocular pressure. There may be dermatologic findings, including perianal/perioral dermatitis (“huffer rash”), frostbite, and contact dermatitis, as well as epistaxis, nasal ulcers, and conjunctivitis.

Table 140.15

Stages in Symptom Development After Use of Inhalants

STAGE	SYMPTOMS
1: Excitatory	Euphoria, excitation, exhilaration, dizziness, hallucinations, sneezing, coughing, excess salivation, intolerance to light, nausea and vomiting, flushed skin and bizarre behavior
2: Early CNS depression	Confusion, disorientation, dullness, loss of self-control, ringing or buzzing in the head, blurred or double vision, cramps, headache, insensitivity to pain, and pallor or paleness
3: Medium CNS depression	Drowsiness, muscular uncoordination, slurred speech, depressed reflexes, and nystagmus or rapid involuntary oscillation of the eyeballs
4: Late CNS depression	Unconsciousness that may be accompanied by bizarre dreams, epileptiform seizures, and EEG changes

CNS, Central nervous system; EEG, electroencephalogram.

From Harris D: Volatile substance abuse, *Arch Dis Child Educ Pract Ed* 91:ep93-ep100, 2006.

Complications

Model airplane glue is responsible for a wide range of complications, related to chemical toxicity, to the method of administration (in plastic bags, with resultant suffocation), and to the dangerous setting in which the inhalation occurs (inner-city roof tops). Common neuromuscular changes reported in chronic inhalant abusers include difficulty coordinating movement, gait disorders, muscle tremors, and spasticity, particularly in the legs (Table 140.16). Chronic use may cause pulmonary hypertension, restrictive lung defects or reduced diffusion capacity, peripheral neuropathy, hematuria, tubular acidosis, and possibly cerebral and cerebellar atrophy. Chronic inhalant abuse has long been linked to widespread brain damage and cognitive abnormalities that can range from mild impairment (poor memory, decreased learning ability) to severe dementia. High-frequency inhalant users were significantly more likely than moderate- and low-frequency users to experience adverse consequences of inhalant intoxication, such as behavioral, language, and memory problems. Certain risky behaviors and consequences, such as engaging in unprotected sex or fighting while high on inhalants, were dramatically more common among high-frequency than low-frequency inhalant users. Death in the acute phase may result from cerebral or pulmonary edema or myocardial involvement (Table 140.16).

Table 140.16

Documented Clinical Presentations of Acute and Chronic Volatile Substance Abuse

Ventricular fibrillation	Muscle weakness
Asystolic cardiac arrest	Abdominal pain
Myocardial infarction	Cough
Ataxia	Aspiration pneumonia
Agitation	Chemical pneumonitis
Limb and trunk uncoordination	Coma
Tremor	Visual and auditory hallucinations
Visual loss	Acute delusions
Tinnitus	Nausea and vomiting
Dysarthria	Pulmonary edema
Vertigo	Photophobia
Hyperreflexia	Rash
Acute confusional state	Jaundice
Conjunctivitis	Anorexia
Acute paranoia	Slurred speech
Depression	Diarrhea
Oral and nasal mucosal ulceration	Weight loss
Halitosis	Epistaxis
Convulsions/fits	Rhinitis
Headache	Cerebral edema
Peripheral neuropathy	Visual loss
Methemoglobinemia	Burns
Acute trauma	Renal tubular acidosis

Diagnosis

Diagnosis of inhalant abuse is difficult because of the ubiquitous nature of the products and decreased parental awareness of the dangers. In the primary care setting, providers need to ask parents if they have witnessed any unusual behaviors in their teen; noticed high-risk products in the teen's bedroom; seen paint on the teen's hands, nose, or mouth; or found paint- or chemical-coated rags. Complete blood count, coagulation studies, and hepatic and renal function studies may identify the complications. In extreme intoxication, a user may manifest symptoms of restlessness, general muscle weakness, dysarthria, nystagmus, disruptive behavior, and occasionally hallucinations. Toluene is excreted rapidly in the urine as hippuric acid, with the residual detectable in the serum by gas chromatography.

Treatment

Treatment is generally supportive and directed toward control of arrhythmia and stabilization of respirations and circulation. Withdrawal symptoms do not usually occur.

140.5

Hallucinogens

Cora Collette Breuner

Keywords

LSD
MDMA
PCP

Several naturally occurring and synthetic substances are used by adolescents for their hallucinogenic properties. They have chemical structures similar to neurotransmitters such as serotonin, but their exact mechanism of action remains unclear. Lysergic acid diethylamide (**LSD**) and methylenedioxymethamphetamine (**MDMA**) are the most commonly reported hallucinogens used. 251-NBOMe (“N-Bomb”) is a new designer drug that interacts with the 5HT-2a receptor and has sympathomimetic and hallucinogenic properties.

Lysergic Acid Diethylamide

LSD (acid, big “d,” blotters) is a very potent hallucinogen that is made from lysergic acid found in ergot, a fungus that grows on rye and other grains. Its high potency allows effective doses to be applied to absorbent paper, or it can be taken as a liquid or a tablet. The onset of action can be 30-60 min, and it peaks at 2-4 hr. By 10-12 hr, individuals return to the predrug state. Among U.S. 12th graders, 4% report trying LSD at least once.

Clinical Manifestations

The effects of LSD can be divided into 3 categories: somatic (physical effects), perceptual (altered changes in vision and hearing), and psychic (changes in sensorium). The common somatic symptoms are dizziness, dilated pupils, nausea, flushing, elevated temperature, and tachycardia. The sensation of *synesthesia,* or "seeing" smells and "hearing" colors, as well as major distortions of time and self, have been reported with high doses of LSD. Delusional ideation, body distortion, and suspiciousness to the point of toxic psychosis are the more serious of the psychic symptoms. LSD is not considered to be an addictive drug because it does not typically produce drug-seeking behavior.

Treatment

An individual is considered to have a "bad trip" when the sensory experiences causes the user to become terrified or panicked. These episodes should be treated by removing the individual from the aggravating situation and placing him in a quiet room with a calming friend. In situations of extreme agitation or seizures, use of benzodiazepines may be warranted. "Flashbacks" or LSD-induced states after the drug has worn off and tolerance to the effects of the drug are additional complications of its use.

Methylenedioxymethamphetamine

MDMA ("X," Ecstasy, Molly), a phenylisopropylamine hallucinogen, is a synthetic compound similar to hallucinogenic mescaline and the stimulant methamphetamine. Like other hallucinogens, this drug is proposed to interact with serotoninergic neurons in the central nervous system (CNS). It is the preferred drug at "raves," all-night dance parties, and is also known as one of the "club drugs" along with γ-hydroxybutyrate (GHB) and ketamine (see Table 140.5). Between 2009 and 2010, past-year use of MDMA increased among U.S. 8th and 10th graders but then declined in both grades. Nationwide, the prevalence of having ever used MDMA was 8.4% of college students. In 2016, MDMA use by blacks (2.2%) in 12th grade was lower than for Hispanics (2.8%) or whites (3.3%).

Clinical Manifestations

Euphoria, a heightened sensual awareness, and increased psychic and emotional energy are acute effects. Compared to other hallucinogens, MDMA is less likely to produce emotional lability, depersonalization, and disturbances of thought. Nausea, jaw clenching, teeth grinding, and blurred vision are somatic symptoms, whereas anxiety, panic attacks, and psychosis are the adverse psychiatric outcomes. A few deaths have been reported after ingestion of the drug. In high doses, MDMA can interfere with the body's ability to regulate temperature. The resultant hyperthermia in association with vigorous dancing at a “rave” has resulted in severe liver, kidney, and cardiovascular system failure and death. There are no specific treatment regimens recommended for acute toxicity.

Chronic MDMA use can lead to changes in brain function, affecting cognitive tasks and memory. These symptoms may occur because of MDMA's effects on neurons that use serotonin as a neurotransmitter. The serotonin system plays an important role in regulating mood, aggression, sexual activity, sleep, and sensitivity to pain. A high rate of dependence has been found among MDMA users. MDMA exposure may be associated with long-term neurotoxicity and damage to serotonin-containing neurons. In nonhuman primates, exposure to MDMA for only 4 days caused damage to serotonin nerve terminals that was evident 6-7 yr later. There are no specific pharmacologic treatments for MDMA addiction. Drug abuse recovery groups are recommended.

Phencyclidine

Phencyclidine (**PCP**) (sternyl, angel dust, hog, peace pill, sheets) is an arylcyclohexalamine whose popularity is related in part to its ease of synthesis in home laboratories. One of the by-products of home synthesis causes cramps, diarrhea, and hematemesis. It is a “dissociative drug” that produces feelings of detachment from the surrounding environment and self. The drug is thought to potentiate adrenergic effects by inhibiting neuronal reuptake of catecholamines. PCP is available as a tablet, liquid, or powder, which may be used alone or sprinkled on cigarettes (joints). The powders and tablets generally contain 2-6 mg of PCP, whereas joints average 1 mg for every 150 mg of tobacco leaves, or approximately 30-50 mg per joint. The prevalence of PCP use (hallucinogenic drug) among U.S. 12th graders was 1.3%.

Clinical Manifestations

The clinical manifestations are dose related and produce alterations of perception, behavior, and autonomic functions. Euphoria, nystagmus, ataxia, and emotional lability occur within 2-3 min after smoking 1-5 mg and last for 4-6 hr. At these low doses the user is likely to experience shallow breathing, flushing, generalized numbness of extremities, and loss of motor coordination. Hallucinations may involve bizarre distortions of body image that often precipitate panic reactions. With doses of 5-15 mg, a toxic psychosis may occur, with disorientation, hypersalivation, and abusive language lasting for >1 hr. Hypotension, generalized seizures, and cardiac arrhythmias typically occur with plasma concentrations of 40-200 mg/dL. Death has been reported during psychotic delirium, from hypertension, hypotension, hypothermia, seizures, and trauma. The **coma** of PCP may be distinguished from that of the opiates by the absence of respiratory depression; the presence of muscle rigidity, hyperreflexia, and nystagmus; and lack of response to naloxone. PCP psychosis may be difficult to distinguish from schizophrenia. In the absence of a history of use, the diagnosis depends on urinalysis.

Treatment

Management of the PCP-intoxicated patient includes placement in a darkened, quiet room on a floor pad, safe from injury. Acute alcohol intoxication may also be present. For recent oral ingestion, gastric absorption is poor, and induction of emesis or gastric lavage is useful. Diazepam, in a dose of 5-10 mg orally or 2-5 mg intravenously, may be helpful if the patient is agitated and not comatose. Rapid excretion of the drug is promoted by acidification of the urine. Supportive therapy of the comatose patient is indicated with particular attention to hydration, which may be compromised by PCP-induced diuresis. Inpatient and/or behavioral treatments can be helpful for chronic PCP users.

140.6

Cocaine

Cora Collette Breuner

Cocaine, an alkaloid extracted from the leaves of the South American *Erythroxylum coca*, is supplied as the hydrochloride salt in crystalline form. With **snorting** , it is rapidly absorbed into the bloodstream from the nasal mucosa, detoxified by the liver, and excreted in the urine as benzoylecgonine. Smoking the cocaine alkaloid (**freebasing**) involves inhaling the cocaine vapors in pipes, or cigarettes mixed with tobacco or marijuana. Accidental burns are potential complications of this practice. With **crack** cocaine, the crystallized rock form, the smoker feels “high” in <10 sec. The risk of addiction with this method is higher and more rapidly progressive than from snorting cocaine. Tolerance develops, and the user must increase the dose or change the route of administration, or both, to achieve the same effect. To sustain the high, cocaine users repeatedly use cocaine in short periods of time known as “binges.” Drug dealers often place cocaine in plastic bags or condoms and swallow these containers during transport. Rupture of a container produces a sympathomimetic crisis (see Table 140.6). Cocaine use among U.S. high school students has decreased in the last decade, as noted in the MTF 2016 data, with 3.7% of 12th graders having tried the drug (any route) at least once.

Clinical Manifestations

Cocaine is a strong CNS stimulant that increases dopamine levels by preventing reuptake. Cocaine produces euphoria, increased motor activity, decreased fatigability, and mental alertness. Its sympathomimetic properties are responsible for pupillary dilation, tachycardia, hypertension, and hyperthermia. Snorting cocaine chronically results in loss of sense of smell, nosebleeds, and chronic rhinorrhea. Injecting cocaine increases risk for HIV infection. Chronic abusers experience anxiety, irritability, and sometimes paranoid psychosis. Lethal effects are possible, especially when cocaine is used in combination with other drugs, such as heroin, in an injectable form known as a “speedball.” Cocaine, when taken with alcohol, is metabolized by the liver to produce cocaethylene, a substance that enhances the euphoria and is associated with a greater risk of sudden death than cocaine alone. Pregnant adolescents who use cocaine place their fetus at risk of premature delivery, complications of low birthweight, and possibly developmental disorders.

Treatment

There are no FDA-approved medications for treatment of cocaine addiction. CBT has been shown to be effective when provided in combination with additional services and social support. Oral sustained-release dexamfetamine has been shown to be partially effective in adults with cocaine dependence.

140.7

Amphetamines

Cora Collette Breuner

Methamphetamine, commonly known as “ice,” is a nervous system stimulant and schedule II drug with a high potential for abuse. Most of the methamphetamine currently abused is produced in illegal laboratories. It is a white, odorless, bitter-tasting powder that is particularly popular among adolescents and young adults because of its potency and ease of absorption. It can be ingested orally, smoked, needle-injected, or absorbed across mucous membranes. Amphetamines have multiple CNS effects, including release of neurotransmitters and an indirect catecholamine agonist effect. In recent years, there has been a general decline of methamphetamine use among high school students. In the 2012 MTF Study, 1.1% of 12th graders reported using methamphetamine at least once, reflecting a steady decline in use.

Clinical Manifestations

Methamphetamine rapidly increases the release and blocks the reuptake of dopamine, a powerful “feel good” neurotransmitter (Table 140.17). The effects of amphetamines can be dose related. In small amounts, amphetamine effects resemble other stimulants: increased physical activity, rapid and/or irregular heart rate, increased blood pressure, and decreased appetite. High doses produce slowing of cardiac conduction in the face of ventricular irritability. Hypertensive and hyperpyrexic episodes can occur as seizures (see Table 140.6). Binge effects result in the development of psychotic ideation with the potential for sudden violence. Cerebrovascular damage, psychosis, severe receding of the gums with tooth decay, and infection with HIV and hepatitides B and C can result from long-term use. A withdrawal syndrome is associated with amphetamine use, with early, intermediate, and late phases (Table 140.17). The early phase is characterized as a “crash” phase with depression, agitation, fatigue, and desire for more of the drug. Loss of physical and mental energy, limited interest in the environment, and anhedonia mark the intermediate phase. In the final phase, drug craving returns, often triggered by particular situations or objects.

Table 140.17

Signs and Symptoms of Intoxication and Withdrawal

	OPIATES	AMPHETAMINES/COCAINE	BENZODIAZEPINES
INTOXICATION			
Behavior	Apathy and sedation; disinhibition; psychomotor retardation; impaired attention and judgment	Euphoria and sensation of increased energy; hypervigilance; grandiosity, aggression, argumentative; labile mood; repetitive stereotyped behaviors; hallucinations, usually with intact orientation; paranoid ideation; interference with personal functioning	Euphoria; apathy and sedation; abusiveness or aggression; labile mood; impaired attention; anterograde amnesia; impaired psychomotor performance; interference with personal functioning
Signs	Drowsiness; slurred speech; pupillary constriction (except anoxia from severe overdose—dilation); decreased level of consciousness	Dilated pupils; tachycardia (occasionally bradycardia, cardiac arrhythmias); hypertension; nausea/vomiting; sweating and chills; evidence of	Unsteady gait; difficulty in standing; slurred speech; nystagmus; decreased level consciousness; erythematous skin lesions or blisters

		weight loss; dilated pupils; chest pain; convulsions	
Overdose	Respiratory depression; hypothermia	Sympathomimetic symptoms	Hypotension; hyperthermia; depression of gag reflex; coma
Withdrawal	Craving to use; lacrimation; yawning; rhinorrhea/sneezing; muscle aches or cramps; abdominal cramps; nausea/vomiting/diarrhea; sweating; dilated pupils; anorexia; irritability; tremor; piloerection/chills; restlessness; disturbed sleep	Dysphoric mood (sadness/anhedonia); lethargy and fatigue; psychomotor retardation or agitation; craving; increased appetite; insomnia or hypersomnia; bizarre or unpleasant dreams	Tremor of tongue, eyelids, or outstretched hands; nausea or vomiting; tachycardia; postural hypotension; psychomotor agitation; headache; insomnia; malaise or weakness; transient visual, tactile, or auditory hallucinations or illusions; paranoid ideation; grand mal convulsions

From Haber PS, Demirkol A, Lange K, et al: Management of injecting drug users admitted to hospital, *Lancet* 374:1284–1292, 2009.

Treatment

Acute agitation and delusional behaviors can be treated with haloperidol or droperidol. Phenothiazines are contraindicated and may cause a rapid drop in blood pressure or seizure activity. Other supportive treatment consists of a cooling blanket for hyperthermia and treatment of the hypertension and arrhythmias, which may respond to sedation with lorazepam or diazepam. For the chronic user, comprehensive CBT interventions have been demonstrated as effective treatment options.

Stimulant Abuse and Diversion

Cora Collette Breuner

In MTF 2016, 6.4% of 12th graders reported using OTC diet pills in their lifetime, and 2.1% in the past 30 days. These include nonprescription stimulants of 2 general types: pseudoamphetamines, usually sold by internet/mail order, and OTC stimulants, primarily diet and “stay-awake” pills. These drugs usually contain caffeine, ephedrine, and/or phenylpropanolamine. Stay-awake pills were used less often in 2016, with 3.6% of 12th graders reporting lifetime use and a 30-day prevalence of 1.7%. Even fewer students indicated use of look-alike products (2.3% lifetime and 0.9% monthly prevalence).

The *misuse* of a stimulant medication, defined as taking a stimulant not prescribed by a health care provider and not in accordance with health care provider guidance, has been growing over the past 2 decades, with a surge in prevalence rates of nonprescription stimulant use among both adolescents and young adults in the past 10 years. Nonprescription use of methylphenidate (**MPH**) in 2000 was 1.2%, increasing to 2% for MPH and 7.5% for nonprescription mixed amphetamine salts (**AMPs**) in 2015.

The majority of nonprescription stimulant users reported obtaining the drugs by **diversion** , a process for obtaining the drug from peers. Diversion occurs quite often and can begin in childhood, adolescence, or young adulthood. Lifetime rates of diversion ranged from 16–29% of students with stimulant prescriptions. One survey reported that 23.3% of middle and high school students taking prescribed stimulants had been solicited to divert their medication to others at a rate that increased from middle to high school. It has been shown that 54% of college students prescribed stimulants for attention-deficit/hyperactivity disorder (ADHD) had been approached to divert their medication.

In U.S. college students, nonprescription use of stimulants (Ritalin, Adderall, Dexedrine) is more prevalent among particular subgroups (male, white, members of fraternities/sororities, with lower grade point averages, more likely to use alcohol, cigarettes, marijuana, MDMA, or cocaine) and types of colleges (northeastern region, with more competitive admission standards). Lifetime prevalence of nonprescription stimulant use was 6.9% and past-month prevalence 2.1%. According to a survey of 334 ADHD-diagnosed college students taking prescription stimulants, 25% misused their own prescription medications. Scholastic pressures, including the need to succeed academically, and persistent social and financial demands place many students at an increased risk for misuse of various drugs, especially at the end of school terms. A web-based survey of medical and health profession students found that the most common reason for nonprescription stimulant use was to focus and concentrate during studying.

Clinical Manifestations

Misuse of stimulants is associated with psychosis, seizures, myocardial infarction, cardiomyopathy, and even sudden death. Intentional misuse of MPH or AMPs in combination with other substances leads to adverse medical consequences. One study revealed an increase in emergency department (ED) visits involving AMP misuse from 862 in 2006 to 1,489 in 2011. Importantly, 14% of the ED visits for stimulant use were associated with cardiovascular (CV) events. Psychosis includes visual hallucinations, delusions, anorexia, flattening of affect, and insomnia mediated by dopaminergic excess. The CV effects include hypertension, arrhythmias, tachycardia, cardiomyopathy, cardiac dysrhythmias, necrotizing vasculitis, and CV accidents. Case reports include serious CV adverse drug reactions (ADRs), sudden death, and psychiatric disorders. Many patients report sleep difficulties (72%), irritability (62%), dizziness and lightheadedness (35%), headaches (33%), stomach aches (33%), and sadness (25%). Other health risks include loss of appetite, weight loss, and nervousness. Many users are involved in heavy episodic alcohol use while using MPH or AMPs. Most users of MPH or AMPs are unaware of these adverse effects and predominantly “feel good” about taking these medications.

Despite reports that MPH misuse is a healthcare issue, >82% of primary care physicians did not suspect misuse of prescribed ADHD medication in one report, and <1% thought that their patients were diverting prescribed ADHD medication. Improved monitoring for malingering and patient misuse may assist stopping diversion of these medications. ADHD diagnosis should be confirmed in those requesting ADHD medication, and they should be screened for use of other drugs.

Treatment

Treatment for nonprescription stimulant overdose is similar as that for amphetamine overdose. Haloperidol or droperidol is recommended for acute agitation and delusional behaviors. Phenothiazines are contraindicated and may cause a rapid drop in blood pressure or seizure activity. Hyperthermia may require use of a cooling blanket, and sedation with a benzodiazepine is recommended for treatment of the hypertension and arrhythmias. In those with chronic use, inpatient or outpatient substance abuse interventions utilizing CBT has been shown to be the most effective treatment option.

Monitoring of the diversion and misuse of pharmaceutical stimulants must be a priority. More data need to be obtained on the prevalence, patterns, and harmful effects in adolescents and young adults.

140.9

Opiates

Cora Collette Breuner

Heroin is a highly addictive synthetic opiate drug made from a naturally occurring substance (**morphine**) in the opium poppy plant. It is a white or brown powder that can be injected (intravenously or subcutaneously), snorted/sniffed, or smoked. Intravenous (IV) injection produces an immediate effect, whereas effects from the subcutaneous route occur in minutes, and from snorting, in 30 minutes. After injection, heroin crosses the blood-brain barrier, is converted to morphine, and binds to opiate receptors. Tolerance develops to the euphoric effect, and the chronic user must take more heroin to achieve the same intense effect. Heroin use among U.S. teens peaked in the mid-1990s but is resurgent in some suburban communities, as is the use of **prescription opioids** found in the home. Nationwide, 2.9% of high school students report having tried heroin at least once. Highest use is seen in black males, with a growing prevalence in suburban high school students; ranges vary from 0.8% to 5.3% across large urban, suburban, and rural school districts. **Fentanyl** is a more potent opiate and is responsible for many opiate overdoses. *Recreational (illegal) use of prescription opiate medications by oral or injection (dissolving the pill) is a major source of opiate addiction and opiate overdoses.*

Clinical Manifestations

The clinical manifestations are determined by the purity of the heroin or its adulterants, combined with the route of administration. The immediate effects include euphoria, diminution in pain, flushing of the skin, and pinpoint pupils (see Table 140.17). An effect on the hypothalamus is suggested by the lowering of body temperature. The most common dermatologic lesions are the “tracks,” the hypertrophic linear scars that follow the course of large veins. Smaller, discrete peripheral scars, resembling healed insect bites, may be easily overlooked. The adolescent who injects heroin subcutaneously may have fat necrosis, lipodystrophy, and atrophy over portions of the extremities. Attempts to conceal these stigmata may include amateur tattoos in unusual sites. Skin abscesses secondary to unsterile techniques of drug administration are usually found. There is a loss of libido; the mechanism is unknown. The chronic heroin user may resort to prostitution to support the habit, thus increasing the risk of sexually transmitted diseases (including HIV), pregnancy, and other infectious diseases. Constipation results from decreased smooth muscle propulsive contractions and increased anal sphincter tone. The absence of sterile technique in injection may lead to cerebral microabscesses or endocarditis, usually caused by *Staphylococcus aureus* or *Pseudomonas aeruginosa.* Abnormal serologic reactions are also common, including false-positive Venereal Disease Research Laboratories and latex fixation tests. Infectious complications are usually not seen with oral prescription opioid use unless the pills are dissolved and injected.

Withdrawal

After ≥8 hr without heroin, the addicted individual undergoes a series of physiologic disturbances over 24-36 hr, referred to collectively as “withdrawal” or the **abstinence syndrome** (see Table 140.17). The earliest sign is yawning, followed by lacrimation, mydriasis, restlessness, insomnia, “goose flesh,” cramping of the voluntary musculature, bone pain, hyperactive bowel sounds and diarrhea, tachycardia, and systolic hypertension. Although the administration of methadone is the most common method of detoxification, the addition of **buprenorphine** , an opiate agonist-antagonist, is available for detoxification and maintenance treatment of heroin and other opiates. Buprenorphine has the advantage of offering less risk of addiction, overdose, and withdrawal effects, and can be dispensed in the privacy of a physician's office.

Combined with behavioral interventions, it has a greater success rate of detoxification. A combination drug, buprenorphine plus naloxone, has been formulated to minimize abuse during detoxification. Clonidine and tramadol have also been used to manage opioid withdrawal.

Drugs used to treat **opioid use disorder** , a chronic relapsing problem, traditionally include methadone maintenance and buprenorphine. Abuse-deterrent opioid pill formulations (when pain control requires an opioid) include pills resistant to crushing that form a viscous gel when dissolved or pills with a sequestered opioid antagonist (naltrexone).

Overdose Syndrome

The overdose syndrome is an acute reaction after administration of an opiate. It is the leading cause of death among drug users. The clinical signs include stupor or coma, seizures, miotic pupils (unless severe anoxia has occurred), respiratory depression, cyanosis, and pulmonary edema. The differential diagnosis includes CNS trauma, diabetic coma, hepatic (and other) encephalopathy, Reye syndrome, and overdose of alcohol, barbiturates, PCP, or methadone. Diagnosis of opiate toxicity is facilitated by IV administration of naloxone, 0.01 mg/kg (2 mg is a common initial dose for an adolescent), which causes dilation of pupils constricted by the opiate. Diagnosis is confirmed by the finding of morphine in the serum.

Treatment

Treatment of acute heroin overdose consists of maintaining adequate oxygenation and continued administration of **naloxone** , a pure opioid antagonist. It may be given intravenously, intramuscularly, subcutaneously, as a nasal spray, or by endotracheal tube. Naloxone has an ultrarapid onset of action (1 min) and duration of action of 20-60 min. Naloxone is often available in the field, carried by first responders. Take-home naloxone may also be given to drug users, their family, or friends; such programs have been effective in treating overdoses. If there is no response, other etiologies for the respiratory depression must be explored. Naloxone may have to be continued for 24 hr if methadone, rather than shorter-acting heroin, has been taken. Admission to the intensive care unit is indicated for patients who require continuous naloxone infusions (rebound coma, respiratory depression) and for those with life-threatening arrhythmias, shock, and seizures.

140.10

Bath Salts

Cora Collette Breuner

Bath salts refers to a group of previously OTC, but now illicit, substances containing 1 or more synthetic chemicals similar to **cathinone** , an amphetamine-like stimulant found in the khat plant. The bath salts, marketed under brand names (e.g., Lunar Wave, Cloud Nine, Vanilla Sky), are sold online or in drug paraphernalia stores as a white or brown crystalline powder and can be ingested, inhaled, or injected. The most current information about teen use of bath salts is from the 2016 MTF survey of 8th, 10th, and 12th graders, who report use of 0.9%, 0.8%, and 0.8%, respectively. The synthetic cathinones found in bath salts include methylone, mephedrone, and 3,4-methylenedioxypyrovalerone (MDPV), all of which are chemically similar to amphetamines and MDMA (Ecstasy).

Clinical Manifestations

The chemicals in bath salts raise brain dopamine levels, causing the user to feel a surge of euphoria, with increased sociability and sex drive. In addition, the user may experience a surge in norepinephrine, causing reactions such as an elevated heart rate, chest pain, vasoconstriction, diaphoresis, hyperthermia, dilated pupils, seizures, arrhythmias, and high blood pressure. Users also experience psychiatric symptoms such as aggressive behavior, panic attacks, paranoia, psychosis, delirium, self-mutilation, and hallucinations caused by elevated serotonin levels. Intoxication from bath salts may cause **excited delirium syndrome** , which includes dehydration, rhabdomyolysis, and kidney failure.

Treatment

Treatment of overdose should be directed at specific complications but often includes benzodiazepines or propofol for agitation and other neuropsychiatric manifestations. The synthetic cathinones in bath salts are highly addictive, triggering intense cravings in those who consume them frequently. This may result in dependence, tolerance, and strong withdrawal symptoms, as seen in other highly addictive substances. The sale of 2 of the synthetic cathinones, mephedrone and MDPV, is illegal in the United States.

CHAPTER 141

The Breast

Cynthia M. Holland-Hall

Breast development is often the first visible sign of puberty in the adolescent female. Pediatric practitioners must be able to distinguish normal breast development, including normal variants, from pathologic breast disorders. Visual inspection of the breast tissue should routinely be a component of the young adolescent's general physical examination. Breast development during puberty is described using the **Sexual Maturity Rating (SMR)** scale, progressing from SMR 1 to SMR 5 as the breast becomes more mature (see Chapter 132 , Fig. 132.2).

Female Disorders

See Chapter 566 .

Male Disorders

Pubertal gynecomastia occurs in up to 65% of healthy adolescent males (see Chapter 603). Although this finding has long been attributed to a transient imbalance of estrogen and androgen concentrations, this biochemical imbalance has not been clearly demonstrated. Recent studies suggest that elevations of insulin-like growth factor (IGF)-I may have a stronger association. Onset typically is between 10 and 13 yr, peaking at SMR 3-4. Careful physical examination is essential to distinguish between **true gynecomastia** , characterized by a discrete disk of palpable glandular tissue under the nipple-areolar complex, and **pseudogynecomastia** , characterized by more diffuse, bilateral adiposity of the anterior chest wall. Physiologic gynecomastia regresses spontaneously in up to 90% of adolescents within 18-24 mo. Reassurance and continued observation are recommended in most patients; surgery may be indicated in severe or persistent cases. No medical therapies for gynecomastia have been approved for use in adolescents by the U.S. Food and Drug Administration. Small, noncontrolled trials of antiestrogens, such as tamoxifen, appear promising, but more evidence is needed. Conditions associated with nonphysiologic gynecomastia include endocrine disorders, liver disease, neoplasms, chronic disease, and trauma. Although dozens of medications are implicated as possible causes of gynecomastia, convincing evidence exists only for a few, including several antiandrogens and other exogenous hormones, antiretrovirals, and histamine$_2$ receptor blockers. Calcium channel blockers, certain antipsychotics, proton pump inhibitors, lavender, and tea tree oil may be causative. Among drugs of abuse, alcohol, opioids, and anabolic steroids may be associated with gynecomastia, but minimal evidence supports an association with marijuana or amphetamines.

Other breast pathology in males is uncommon. Benign masses such as neurofibromas, lipomas, and dermoid cysts have been reported in the male breast. Males with Klinefelter syndrome have an elevated risk of breast cancer (see Chapter 601), but this malignancy is otherwise exceedingly rare in adolescents.

CHAPTER 142

Menstrual Problems

Krishna K. Upadhya, Gina S. Sucato

See also Chapter 565 .

Menstrual disturbances, including delayed onset, irregularity, heavy flow, and pain, occur in 75% of females during adolescence. Menstrual problems vary in presentation. For adolescents with minor variations from normal (Table 142.1), an explanation of symptoms and reassurance may be all that is needed. Severe dysmenorrhea or prolonged menstrual bleeding can be not only frightening, but a cause of persistent morbidity requiring more aggressive management, potentially including referral to a specialist in adolescent gynecology.

Table 142.1

Characteristics of Normal Menses[*]

Cycle length	21-35 days from the 1st day of one period to the 1st day of the next (during 1st 3 yr after menarche can be 21-45 days)
Duration of menses	7 or fewer days
Blood flow	6 or fewer (soaked) pads or tampons per day

[*] Adolescents with 2 or more cycles outside this range or who skip their period for 3 consecutive mo warrant evaluation.

Normal Menstruation

Data from many countries, including the United States, suggest that the average age of menarche, or first menses, varies according to ethnic origin and socioeconomic status. There is often a close concordance of the age at menarche between mother and daughter, suggesting that genetic factors are determinants in addition to individual factors such as weight, exercise level, and chronic medical conditions. The age of menarche has declined in countries and populations experiencing improved nutritional standards and other living conditions. In U.S. females, the average age of menarche, 12.5 years, has been relatively stable over the last few decades; it is slightly older for non-Hispanic whites, and slightly younger for non-Hispanic blacks and Hispanic Americans.

Menarche typically occurs within 2-3 yr of the onset of breast budding (**thelarche**), which is the 1st sign of puberty in most females. Menarche usually occurs during breast **sexual maturity rating** (**SMR** ; i.e., Tanner stage) 4. Periods gradually become more regular, initially with longer cycle lengths ranging between 21 and 45 days. The older the age at which menarche occurs, the longer it takes for consistently ovulatory cycles to be established. However, for most adolescents, by 3 yr after menarche, menstrual cycles are similar to that of adults: between 21 and 35 days long.

Menstrual Irregularities

In young adolescents, many variations in menstruation are explained by **anovulation** that results from immaturity of the hypothalamic-pituitary-ovarian axis governing menstrual cyclicity. Significant deviations from normal should prompt a search for organic pathology in a logical and cost-effective manner. An accurate menstrual history is an important, but often lacking, 1st step toward a diagnosis. At menarche, all patients should be encouraged to track their periods, which several free smartphone and tablet applications can facilitate.

Previously, a range of terms has been used to describe abnormal menstrual bleeding. These include “menorrhagia” to indicate regularly occurring bleeding that was excessive in amount or duration, and “metrorrhagia” to indicate irregular bleeding between periods. Such terms are imprecise, confusing, and not linked to any specific underlying pathology. **Abnormal uterine bleeding (AUB)** is the preferred term for uterine bleeding that is abnormal in regularity, volume, frequency, or duration. AUB is further specified by adding terms that describe the bleeding as heavy *menstrual* bleeding, or *intermenstrual* bleeding. A qualifying letter is added to indicate the etiology of the abnormal bleeding. Of the 9 categories of etiologies, the 3 most relevant to adolescents are **ovulatory dysfunction** (AUB-**O**), previously referred to as “dysfunctional uterine bleeding” and discussed in Chapter 142.2 ; **coagulopathy** (AUB-**C**); and **not yet classified** (AUB-**N**).

In addition to a standard medical history noting hospitalizations, chronic illness, and medication use, a complete history for evaluating a patient with menstrual irregularity should include the timing of pubertal milestones, such as onset of pubic and axillary hair and breast development; a detailed patient menstrual history; age of menarche and overall menstrual pattern of mother and sisters; and a family history of gynecologic problems. The complete review of systems should elicit any changes in headache pattern or vision; the presence of galactorrhea; and any changes in skin, hair, or bowel patterns. Changes in diet, level of exercise, and sports participation are also important factors when generating a differential diagnosis. As with all adolescent visits, the patient should be interviewed alone, and the confidential history should assess substance use, consensual sexual activity, forced sexual behavior, abuse, and other psychosocial stressors.

In addition to the basic growth parameters of weight, height, blood pressure, heart rate, and body mass index, a careful review of the patient's growth chart is indicated. Physical examination should document SMR; signs of androgen excess, such as hirsutism or severe acne; and signs suggestive of an eating disorder (see Chapter 41), such as lanugo or knuckle calluses. A careful external genital examination should be performed, but in the absence of sexual activity, an internal pelvic examination is rarely necessary. If being considered for the young adolescent, an internal exam should be performed by a physician with expertise in this age-group using proper equipment and technique. Transabdominal pelvic ultrasound can be a useful adjunct for evaluating anatomic abnormalities in the adolescent; when indicated, MRI can provide greater detail of pelvic anatomy.

142.1

Amenorrhea

Krishna K. Upadhya, Gina S. Sucato

Keywords

amenorrhea
polycystic ovary syndrome
PCOS
female athlete triad

Amenorrhea, the absence of menstruation, generally requires evaluation at age 15 yr, or if there has been no menstruation within 3 yr of the onset of puberty (**primary amenorrhea**), or if there has been no menstruation for the length of 3 previous cycles in a postmenarchal patient (**secondary amenorrhea**). However, the following caveats exist: lack of any pubertal signs by age 13 yr in a girl should prompt evaluation for pubertal delay; in sexually active patients, or those with other symptoms suggesting pathology, evaluation should be initiated without waiting for 3 missed cycles; in patients whose breast development started between age 8 and 9 yr, observation for >3 yr may be warranted in some cases, given data suggesting that the age of thelarche has decreased but the age of menarche has not. Conversely, expectant management with close follow-up can be considered in a patient whose history, physical examination (showing some signs of pubertal development), and family history suggest constitutional delay of puberty.

The differential diagnosis of amenorrhea is broad (Table 142.2) and requires a careful history and physical exam to guide any necessary diagnostic studies. Key to the evaluation is understanding the timing and tempo of the patient's pubertal milestones. The evaluation of a patient presenting with amenorrhea should begin by ascertaining whether she has ever had any prior menstrual bleeding. Some aspects of the evaluation of both primary and secondary amenorrhea are identical; conditions that can interrupt the menstrual cycle can also prevent menarche. In females with primary amenorrhea, however, genetic and anatomic conditions must also be considered (Table 142.3).

Table 142.2

Causes of Amenorrhea (Primary or Secondary)

- Pregnancy (regardless of history can cause primary or secondary amenorrhea)
- Functional hypothalamic causes (stress, weight loss, undernutrition, high

- levels of exercise, energy deficit even at normal weight)
- Female athlete triad (inadequate energy intake, amenorrhea, and low bone density)
- Eating disorders
- Premature ovarian insufficiency (autoimmune, idiopathic, galactosemia, or secondary to radiation or chemotherapy)
- Hypothalamic and/or pituitary damage (e.g., irradiation, tumor, traumatic brain injury, surgery, hemochromatosis, midline central nervous system defects such as septooptic dysplasia, autoimmune pituitary hypophysitis)
- Thyroid disease (hyper- or hypo-; hypothyroidism more likely to be associated with increased bleeding)
- Prolactinoma
- Systemic disease (e.g., inflammatory bowel disease, cyanotic congenital heart disease, sickle cell disease, cystic fibrosis, celiac disease)
- Hyperandrogenism (polycystic ovary syndrome, nonclassic congenital adrenal hyperplasia, adrenal tumor or dysfunction)
- Drugs and medications (e.g., illicit drugs, atypical antipsychotics, hormones)
- Turner syndrome (including mosaicism)

Table 142.3

Additional Causes of Primary Amenorrhea

- Physiologic/constitutional delay
- Anatomic abnormalities
    - Müllerian agenesis
    - Imperforate hymen
    - Transverse vaginal septum
- Genetic disorders
    - 46,XY disorders of sexual development (e.g., androgen insensitivity syndrome, 5α-reductase deficiency, 17α-hydroxylase deficiency)
    - Mixed gonadal dysgenesis (associated with a number of different chromosome patterns)
    - Turner syndrome (resulting from 45,X or a variety of mosaic or other abnormal karyotypes)
    - Genetic hypogonadotropic hypogonadism (e.g., X-linked

Kallmann syndrome)

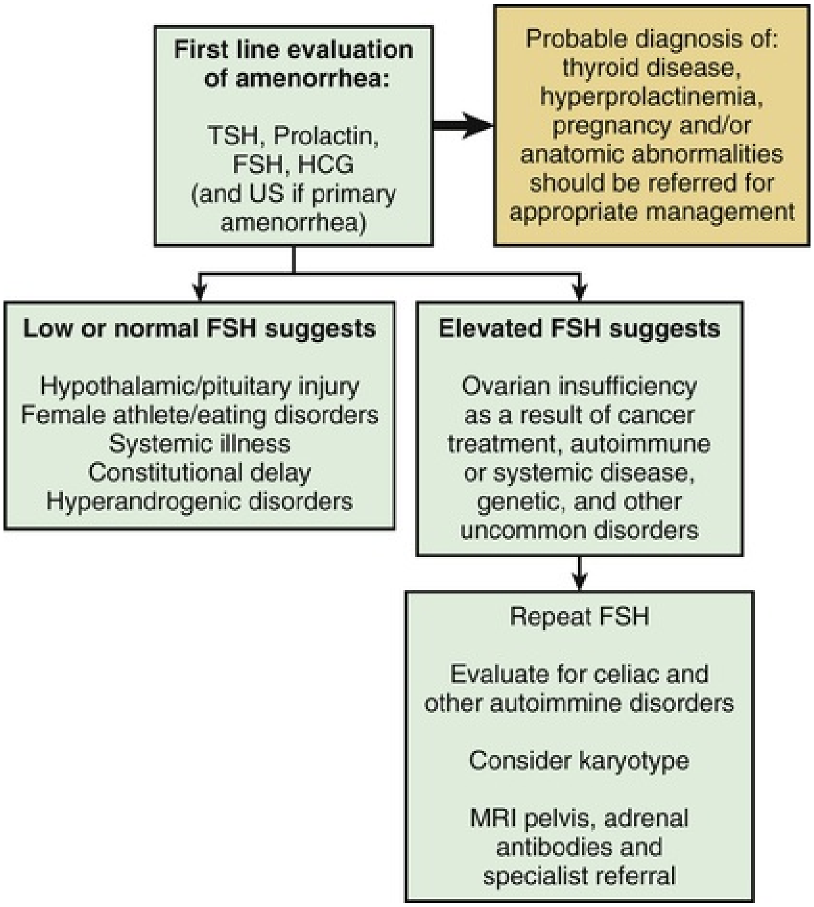
History and Physical Examination

Important elements of the history include dietary intake, exercise level, and a thorough review of any ongoing symptoms, including fever, headache, vision changes, chronic respiratory or gastrointestinal (GI) complaints, changes in bowel history, galactorrhea, changes in hair or nails, excessive body hair, severe acne, unexplained musculoskeletal complaints, and changes in vaginal discharge (which can disappear in females who are hypoestrogenic for reasons such as poor caloric intake). Any underlying medical conditions and the adequacy of their control should be noted, as well as the presence of any renal or skeletal anomalies, some of which may be associated with reproductive system anomalies. Medications, particularly those for psychiatric conditions, should be documented. Family history of menarcheal age, eating disorders (see Chapter 41), and **polycystic ovary syndrome (PCOS** ; see Chapter 567) should be elicited. A thorough social history is necessary, especially concerning the presence or absence of sexual activity or abuse (see Chapter 16.1).

Physical examination should begin with careful attention to growth chart trajectories. In addition to a search for undiagnosed systemic disease, clues to an eating disorder, thyroid disease, or hyperandrogenism should be sought. The exam should assess for body mass index, orthostatic pulses, blood pressure, abnormal dentition, anosmia or hyposmia (suggestive of Kallmann syndrome; see Chapter 601.2), parotid enlargement, thyroid gland palpation, hepatosplenomegaly or other abdominal mass, lymphadenopathy, presence or absence of breast tissue (by palpation, not inspection), and SMR (see Chapter 132). Skin examination should note any lanugo, dry or doughy skin, loss of hair from scalp or eyebrows, striae, acanthosis nigricans, or acne. The genital exam should note SMR and appearance of the vagina, which should be pink and moist; thin, dry, reddened mucosa suggests estrogen deficiency. The clitoral width should be <1 cm. In the patient with primary amenorrhea, vaginal patency can be assessed painlessly using a slender saline-moistened swab and careful avoidance of the hymen. If physical assessment of the cervix and uterus is not tolerated, a pelvic ultrasound is advisable in patients with primary amenorrhea, followed by MRI if more detail is needed.

Laboratory Studies

A urine pregnancy test, serum levels of prolactin, thyroid-stimulating hormone, and follicle-stimulating hormone (FSH) are reasonable to measure in all patients presenting with amenorrhea (Fig. 142.1). Elevation of FSH (>30 mIU/mL) in an amenorrheic female suggests ovarian insufficiency, and if confirmed with repeat testing, should be followed with a pelvic ultrasound, karyotype, and specialist referral. Diagnostic tests in the patient presenting with amenorrhea should be tailored to her history and physical exam (Table 142.4).



First line evaluation of amenorrhea:
TSH, Prolactin, FSH, HCG (and US if primary amenorrhea)
Probable diagnosis of: thyroid disease, hyperprolactinemia, pregnancy and/or anatomic abnormalities should be referred for appropriate management
Low or normal FSH suggests
Hypothalamic/pituitary injury
Female athlete/eating disorders
Systemic illness
Constitutional delay
Hyperandrogenic disorders
Elevated FSH suggests
Ovarian insufficiency as a result of cancer treatment, autoimmune or systemic disease, genetic, and other uncommon disorders
Repeat FSH
Evaluate for celiac and other autoimmine disorders
Consider karyotype
MRI pelvis, adrenal antibodies and specialist referral

FIG. 142.1 Initial diagnostic testing to evaluate amenorrhea. FSH, Follicle-stimulating hormone; HCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging; US, ultrasound.

Table 142.4

Laboratory Tests to Evaluate Patients With

Total and free testosterone[*]
Liver, kidney, and thyroid function studies
Complete blood count with platelets
Urine pregnancy test (regardless of history)
Nucleic acid amplification test (NAAT) or other equivalent testing for *Chlamydia*, gonorrhea, and *Trichomonas*
Prothrombin time and partial thromboplastin time
Ferritin level
Von Willebrand factor antigen, ristocetin cofactor, and factor VIII[†] activities
Pelvic ultrasound (if bleeding persists despite treatment)

---

[*] In patients with signs or symptoms suggestive of polycystic ovary syndrome, such as acne, hirsutism, obesity, acanthosis nigricans, and a history of infrequent menses.

[†] Any abnormalities should be followed with a ristocetin-induced platelet aggregation and von Willebrand factor multimers. Testing in the 1st 3 days of menses and before any estrogen treatment is started minimizes the chances of false-negative tests. Repeat testing can be warranted in patients for whom there is a high pretest suspicion.

In patients with signs of androgen excess (e.g., severe acne or hirsutism) or other physical stigmata associated with PCOS (rapid pubertal weight gain, acanthosis nigricans) consider measuring levels of 17-hydroxyprogesterone (17-OHP) (collected in the morning, approximately 8 AM), free and total testosterone, dehydroepiandrosterone sulfate (DHEAS), and androstenedione. PCOS affects up to 15% of females; diagnostic criteria for adolescents are controversial but include variations of menstrual irregularity (ranging from amenorrhea to AUB) and physical or biochemical evidence of androgen excess. The interpretation of polycystic ovarian morphology identified on ultrasound in adolescents can be challenging, and an ultrasound is not necessary for diagnosis in adolescents.

With the exceptions of pregnancy, constitutional delay, and imperforate hymen, conditions causing primary amenorrhea are associated with reduced fertility; thus their diagnosis may cause profound emotional responses in patients and families. Therefore, before ordering studies to confirm these diagnoses (e.g., karyotype, MRI of reproductive anatomy), the clinician should carefully consider the implications and be prepared to refer to specialists with experience managing the long-term treatment of such diagnoses.

In patients presumed to have hypothalamic amenorrhea, based on prepubertal luteinizing hormone (LH) and low FSH levels using an ultrasensitive assay and consistent history and physical exam, MRI of the brain is not necessary in all patients. However, MRI should be considered for patients presenting with a headache history that is a change from baseline, persistent emesis, change in thirst, urination, or vision, elevated prolactin or galactorrhea, or other neurologic symptoms.

Treatment

Treatment for amenorrhea varies widely depending on the underlying cause. Many diagnoses require referral to clinicians in specialties such as endocrinology, adolescent medicine, gynecology, and other surgical subspecialists; often, collaboration with other disciplines such as psychology or nutrition is also indicated. For patients with **PCOS** , the mainstay of treatment is suppression of ovarian androgens (typically with combined hormonal contraception, i.e., estrogen and progestin) and lifestyle modifications to decrease obesity and insulin resistance. Patients with abnormal glucose tolerance may benefit from the addition of metformin. Spironolactone, an androgen receptor blocker, can also be used to reduce androgen effects, including hirsutism. Because of the high prevalence of **metabolic syndrome** in PCOS, evaluation of comorbid diabetes and hyperlipidemia with periodic lipid screening and oral glucose tolerance testing should be considered, particularly for obese patients, those with familial risk factors, and those with other signs such as acanthosis nigricans and hypertension. For patients with eating disorders or other conditions of energy imbalance that render them hypoestrogenic, normalizing weight and improving nutritional status are the keys to treatment. Initiation of hormonal therapy is not recommended routinely in these patients. However, for those who remain amenorrheic after a trial of nutritional and activity modification, short-term use of **transdermal estrogen therapy** (E2) may be considered to protect bone health. For females with amenorrhea based on ovarian insufficiency (or absence), exogenous hormones are required for all pubertal development. Experts recommend starting at age 10-12 yr with low-dose transdermal estrogen, progressing to increased doses of estrogen and cyclic progestin. Continued maintenance therapy can be accomplished with higher-dose combination products, as found in typical combined hormonal contraceptive pills, patches, and rings.

For patients with **secondary amenorrhea** , use of hormones to bring on monthly bleeding (e.g., with combined hormonal contraception) in the absence of a clear indication (e.g., PCOS, contraception) is not recommended, because this will mask the patient's subsequent menstrual pattern. However, in patients with normal postpubertal estrogen levels, progesterone can be useful to periodically (every 4-12 wk) induce shedding of the endometrial lining to avoid buildup and subsequent heavy menses. One commonly used regimen is medroxyprogesterone, 10 mg daily for the 1st 12 days of the month.

Abnormal Uterine Bleeding

Krishna K. Upadhya, Gina S. Sucato

Keywords

abnormal uterine bleeding
AUB
von Willebrand disease

Abnormal uterine bleeding (AUB) is a broad term used to describe any menstrual bleeding pattern that is outside what is considered physiologic. Clinicians are encouraged to categorize the abnormal pattern based on the patient's complaint, which will usually be menses that are irregular (AUB/**IMB: intermenstrual bleeding**) or heavy (AUB/**HMB: heavy menstrual bleeding**).

Irregular Menstrual Bleeding

The American Academy of Pediatrics (AAP) advocates treating menstrual status as a *vital sign* at routine visits. Although menses are frequently irregular in the early postmenarcheal years, further evaluation is necessary when menstrual patterns vary too widely from what is normal for age. Even in the 1st postmenarcheal year, menses should not be less frequent than every 45 days. Menses become increasingly regular with age, and by 3 years after menarche typically occur every 21-35 days, lasting 3-7 days. An adolescent's personal cycle duration is usually established by age 19 or 20 yr.

Adolescents rarely present with complaints of unusually short or light menses. However, short, light, or infrequent menses should be evaluated similarly to secondary amenorrhea. Females whose menses are excessive are much more likely to come to attention for AUB.

In the early postmenarcheal years, the most common cause of AUB in adolescents is anovulation caused by immaturity of the hypothalamic-pituitary-ovarian axis. In the absence of a mid-cycle surge of LH to stimulate ovulation, there is no corpus luteum production of progesterone. Without the stabilizing effects of progesterone on the endometrial lining, there is increased risk of irregular bleeding. Irregular bleeding because of anovulation, in the absence of anatomic, systemic, or endocrinologic disease, is categorized as **AUB caused by ovulatory dysfunction** (**AUB-O** ; previously referred to as dysfunctional uterine bleeding). Although it is the most common cause of abnormal menstrual bleeding in adolescents, AUB-O is a diagnosis of exclusion. In generating a differential diagnosis, it is important to remember that most conditions that lead to amenorrhea can cause anovulation first, and anovulation is a key risk for heavy irregular bleeding. Table 142.5 lists the causes of AUB.

Table 142.5

Causes of Irregular Menstrual Bleeding/Abnormal Uterine Bleeding (AUB)

CAUSES OF AUB	EXAMPLES	FEATURES
Immature hypothalamic-pituitary-ovarian axis (AUB-O)	Patient within 2 yr of menarche	Painless; patient responds to hormonal treatment.
Weight changes, disordered eating, or excessive exercise	Anorexia nervosa, bulimia, weight gain or loss of more than 10 pounds from any etiology	Weight loss more frequently results in lighter, less frequent menses.
Endocrinologic causes	Thyroid disease, polycystic ovary syndrome (PCOS)	Bleeding typically increases with hypothyroidism and decreases with PCOS and hyperthyroidism.
Complication of pregnancy	Threatened abortion, postpartum or postabortal endometritis	History of sexual activity and/or pregnancy
Infection	Cervicitis, condyloma, pelvic inflammatory disease	Bleeding is usually not heavy and may occur with sexual intercourse.

Trauma	Sexual assault, straddle injuries	History will be evident in patients of menstruating age unless there is cognitive disability.
Vaginal foreign body	Toilet paper, broken condoms, tampons	Associated with odor and vaginal discharge, but usually not heavy bleeding.
Hematologic causes	Von Willebrand disease, platelet function disorder, thrombocytopenia (idiopathic thrombocytopenic purpura, drug induced), hemophilia carriage, clotting factor deficiency, leukemia	Bleeding is heavy and/or long and frequently regular, may present at menarche, and may be accompanied by a suggestive family history (hysterectomy, uterine ablation, cautery for epistaxis) or physical exam (ecchymoses, petechiae).
Medications	Estrogens, progestins, (in pills, patches, rings, injections, implants, and intrauterine devices), androgens, drugs that cause prolactin release (estrogens, phenothiazines, tricyclic antidepressants, metoclopramide), anticoagulants (heparin, warfarin, aspirin, NSAIDs), SSRIs	Affect the hypothalamic-pituitary-ovarian axis, endometrial lining, platelets, or coagulation pathway.
Anatomic	Partial obstruction of vagina or uterus causing asynchronous bleeding; cervical or endometrial polyps or myomas; hemangioma; uterine vascular malformation; genital/reproductive tract cancer	Most of these entities are extremely rare, especially reproductive tract cancers.
Systemic disease	Celiac disease, rheumatoid arthritis, Ehlers-Danlos syndrome	Accompanied by other signs of the condition.

Unscheduled bleeding during the use of hormonal contraception frequently occurs, particularly with progestin-only methods. Common causes include medication nonadherence, interacting medications (prescribed or over-the-counter), and smoking. Patients should be reassured such bleeding is benign and not an indication to stop an otherwise satisfactory contraceptive method.

Heavy and Prolonged Menstrual Bleeding

Irregular bleeding, particularly that resulting from anovulation, can be long and heavy (Table 142.5). However, in patients who have regular, cyclic menses that are long and/or heavy, particularly if menses are heavy from the onset of menarche, a hematologic cause should be strongly considered. **Von Willebrand disease** and coagulation disorders are found in up to 13% and 20%, respectively, of women with heavy menstrual bleeding; prevalence goes up significantly among women with bleeding severe enough to warrant hospitalization. Other symptoms suggestive of bleeding disorders include *flooding* (changing a pad or tampon more than hourly), passing clots larger than 1 inch in diameter, menses longer than 7 days, a history of hemorrhagic ovarian cysts, excessive bleeding from wounds or postoperatively, and first-degree relatives with heavy menses or epistaxis requiring medical treatment.

Laboratory Findings

Table 142.4 lists laboratory tests to be considered in patients with long, heavy bleeding. Females with persistent heavy bleeding despite negative testing should be referred to a hematologist for testing for platelet function disorders, factor deficiencies, and other less common disorders. In the initial evaluation, rapidity of blood loss in conjunction with the hemoglobin establishes the **severity of the bleeding: mild (** hemoglobin > 10 g/dL), **moderate** (hemoglobin 8-10 g/dL), or **severe** (hemoglobin < 8 g/dL).

Treatment

In **mild** bleeding, iron supplementation is recommended, and the patient should keep a menstrual calendar to follow the subsequent flow patterns. Nonsteroidal antiinflammatory drugs (NSAIDs; e.g., naproxen) are more effective than placebo in treating heavy bleeding and also would help treat any concurrent dysmenorrhea. Active bleeding typically responds well to cycling with any combined hormonal contraceptive (containing estrogen and progestin) method starting with twice-daily dosing if needed until bleeding stops. Patients with estrogen contraindications can be treated with progestins alone, such as medroxyprogesterone or norethindrone acetate, 10 mg orally (PO) per day, either continuously or for 12 days per month. The latter regimen will be followed by monthly bleeding.

With **moderate** anemia, any of the hormonal regimens above can be used. However, it may be necessary to start with 3-4 combined oral contraceptive (COC) pills (or 3-4 doses of medroxyprogesterone 10 mg) per day, with additional medication to control nausea. The dose can usually be tapered to daily dosing over the next 2 wk. Patients with ongoing rapid bleeding, syncope or lightheadedness, or hemodynamic instability should be treated in the hospital, as should most patients with a hemoglobin of <8 g/dL.

Patients with **severe** anemia should be treated with 1 of the hormone tapers described above, in addition to fluid or blood products as indicated; it is advisable to draw necessary laboratory studies before transfusion. Patients with emesis or other significant symptoms may be treated initially with conjugated estrogens, 25 mg intravenously (IV) every 4-6 hr for 1-2 days. A COC or progestin regimen should be added within the 1st day because progestin is needed to stabilize the endometrial lining and can be used as maintenance therapy after hospital discharge. In the exceptionally rare case of a patient whose bleeding cannot be controlled hormonally, options for gynecologic interventions include intrauterine Foley balloon placement or uterine packing to tamponade the uterus mechanically. Dilation and curettage, performed frequently in adult women, is almost never indicated in adolescents and can increase blood loss in women with bleeding disorders.

Hormonal treatment for AUB should continue for at least 3-6 mo, depending on the patient's age, prior menstrual history, and severity of presentation, before reassessing the need for ongoing therapy. Additional options for maintenance therapy include combined hormonal transdermal patches and vaginal rings; depot medroxyprogesterone acetate, 150 mg intramuscularly (IM) or 104 mg subcutaneously (SC) every 3 mo; and placement of a levonorgestrel intrauterine device (IUD), depending on the patient's concurrent need for long-term contraception. For patients who choose to avoid hormonal therapy, tranexamic acid, 1,300 mg PO 3 times daily, can be used for up to the 1st 5 days of menses in patients who do not have an increased risk of thrombosis.

For young women with bleeding disorders, formulation of a long-term treatment plan is best done in collaboration with the patient's hematologist. Females with a known bleeding disorder may be up to 5 times more likely to develop heavy menstrual bleeding. Therefore, it can be helpful while the patient is still premenarcheal to put a proactive plan in place in the event of acute heavy menstrual bleeding, which can occur with a patient's first menstrual period.
